Those who have charge of Vines during the growing season should be careful to keep well up to their work. This can be done very easily by forming a resolution to look over them once every week. As the season advances work becomes more and more pressing, throwing one's notions of punctuality rather out of gear. These remarks may be pondered by young gardeners who have charge of hothouses. They know that their work is cut out for them; a certain quantity must be done, and it can only be done well if it is seen to at the right time. Every young gardener should take this saying to himself, "Never leave until to-morrow what can be done to-day." Success in life depends upon the rigid observance of every-day duties. Let us see how these remarks bear upon the cultivation of the Vines and the necessity of looking over them once every week. In the early houses growth is very rapid at the present time, and the shoots have to be gradually brought down to the wires. Very carefully must this be done, else the most vigorous shoots may be broken off at the base, and another one will not be formed, so that an ugly blank will be prominent all the season. I stop the lateral growths two leaves beyond the bunch, and this is done as soon as the point can be taken out with the finger and thumb. Very soon other laterals will be produced from the base of each leaf-stalk, and these also should be pinched out to one leaf, and they can only be kept well under control by weekly attention. The points of the shoots to be pinched out should not be allowed to run out more than an inch or two. The smaller the quantity of leaves removed so much the better for the Vines. It is not uncommon to see superfluous laterals allowed to grow as much as 2 feet and 3 feet, and armfuls of them are cut out at one time; whereas they ought to have been removed in a handful or two. I remember the late Mr. J. R. Pearson, of Chilwell, who was a most ardent cultivator of the Vine, stating that he believed shanking was caused by the shock to the system of the Vine, brought about by this evil practice of allowing the laterals to grow too much, and then cutting them all off at one time. The mi-chief might not be discerned the first, or even the second, year of the practice of it, but that it ultimately tells upon the constitution of the Vines I have no doubt. Punctuality is equally necessary as regards the thinning out of the berries. Ten days after the first flowers open, thinning should commence, and all the berries intended to be removed should be taken out at one time. Those who have not much experience

of this work are apt to leave too many berries, and when they attempt to go over the bunches a second time they thin out too many berries from the upper part of the shoulders. When the bunches are all thinned and the berries rapidly swelling, the laterals do not grow very freely, but pinching must still be continued, the object of the cultivator being to prevent any over-crowding of the leaves. It is well to remember, too, that Black Hamburgh Grapes colour best when moderately shaded by the leaves, but Muscats ought to be rather freely exposed to sunlight.

J. DOUGLAS.

APPLES.

WHILST such gloomy contemplations concerning the large imports of foreign Apples are being indulged in, it is worth noting the splendid promise found on the trees this season, for almost universally the buds are large, plentiful, and evidently capable of presently producing a grand display of bloom. We might have had in the Apple bloom that which was as colourless or small as that of the Plum or the Whitethorn. Happily, such is not the case, and even if no fruit follows, we get some enjoyment from a glorious feast of Apple blossom in its season. That alone would not, however, repay for orchard planting. There is indeed good reason, now that the trees promise so admirably and the season is so late, to believe that the joys of spring bloom and of autumn cropping will this year be realised to the full. "G. H. E.," in discussing the subject of English *v.* American Apples, recently went a little out of his way to charge me with an excess of patriotism because I thought English Apples were after all the best. It was a rather absurd notion, and quite outside the topic being discussed. I rather based my estimate of the merits of the respective fruits, home and foreign, upon a wide experience of Canadian Apples gained at South Kensington in October last, when one of the finest collections of Apples from the Dominion was staged in the conservatory, and beautiful as they were, superb in size, colour, and finish, yet not one was equal in quality to our best English Apples. Such was the opinion, not merely of myself, but of a body of experts. However, I have urged that the best test of the respective merits of these American Apples with our own would be found after Christmas and early in the year. I suggested that the fruit committee of the Royal Horticultural Society, having special advantages, should obtain both home and American samples, and test them for quality occasionally. That there were recently plenty of good Apples of home growth in the country was evidenced at Chester, and it is morally certain that had the committee but invited samples for the purpose named, plenty would have been forthcoming. Mr. Coleman unearthed a comparatively unknown Apple in Pomeroy as a really good winter variety. Possibly there may be many others, but we want to know how far we fail at present in the production of good Apples, which only want to be known to be widely grown. If we should get a heavy crop of Apples this year, might it not prove worth while to promote a company, the object of which should be to purchase whilst cheap all the best samples of keeping Apples, properly store or tub them, and then see how far it would be possible to oppose American Apples with selected or picked home-grown fruits. Unfortunately, we take ten years to perform what the quick-witted Americans would do in as many months.

A. D.

Spur-pruning Grosse Mignonne.—My advice to "X." (p. 301), who complains of this Peach being a poor bearer, is to grub it up and fling it on the rubbish-heap. If you happen to get it true (which is not at all a sure thing, as there are no fruits so much mixed in nurseries), you will find that it is a good grower, free from insects and other pests, and never bears any fruit worth speaking of, and what it does bear is inferior compared to some varieties. I know it well, having a fine tree of it at one time that grew and flowered well, but never bore any

crop worth mentioning, and I grubbed it up. It is the worst bearing Peach in cultivation, and very tender skinned. I would advise all nurserymen to exterminate it wherever found. Well grown, you cannot find a finer flavoured Peach than Royal George, nor one that bears so well and constantly; and Walbarton Admirable is a later one, equally fine in every way. Since writing the above, I see Mr. Coleman praises the Grosse Mignonne. Is he sure he has it true? I have had more difficulty in getting Peaches true than almost any other fruit, but I believe my Grosse Mignonne was true. It is a large-flowered kind, and the skin is so tender that the fruit will hardly bear handling. — S. W.

LABELLING FRUIT TREES.

MANY disappointments would be avoided if this important item was better attended to both by nurserymen and gardeners. If more attention was paid to the subject, gardeners would be less ignorant as to the names of fruit, for, as a rule, pomological knowledge is not so extensively disseminated amongst gardeners, and a less number of boxes of fruit would be sent to our obliging editors, accordingly less work for their already over-taxed brains. It is gratifying to know we have some nurserymen who devote the greater part of their time to the culture of fruit trees, and do their best to have them correctly named, but the practice adopted by a certain class of nurserymen is far from conducive to correct naming. Someone from the nursery is perhaps sent to some gardening friend close at hand for grafts, or perhaps some are sent to them from different parts of the country, and whatever name is given with the grafts, is of course, affixed to the young trees without any inquiry as to its correctness. Again, the grafting in some nurseries is too often performed by men who care little whether they affix the right label or not, and then such trees are sent out to customers as being correctly named, thereby contributing much towards the evil complained of, for very few nurserymen plant out trees of each sort specially for fruiting in order to prove the correctness of the nomenclature, and, as a rule, such as do fruit in their nursery quarters have the fruit taken off at an early stage for the purpose of encouraging as much growth as possible. Not long ago I saw a consignment of fruit trees opened that had just arrived from a nursery, and amongst a bundle of supposed correctly named Apple trees a Pear tree was found having a name of an Apple affixed to it. When such a thing occurs there exist grave doubts as to the correctness of the names of the other trees, but as none of the trees mentioned have yet fruited it is difficult to say whether such is the case or not. When fruit trees are received from nurseries the labels attached to them are often of the flimsiest description, many being merely slips of paper, and others being narrow strips of wood tied to a branch with a small piece of string. Such labels ought to be regarded as merely temporary, and should be replaced by a more durable article at the earliest convenience.

Much has been written as to which is the most durable material for labels, some preferring one thing and some another. Zinc is an excellent material, possessing lightness, cheapness, and durability. The name should be written with indelible ink, and the label suspended from the tree by copper wire. It will last for years, and at the pruning season a glance will show whether the wood has swelled and the wire is cutting the bark. Even good stout wood labels may be used if well painted and renewed every two or three years, but they should be fastened on with wire, for if string and bad wood are used the string decays and the label falls to the

ground, and is either dug into the soil or raked off with the leaves and weeds and wheeled to the rubbish heap, or if made of bad wood and not renewed every year or so, the names become illegible. In the case of wall trees the labels can be nailed on to the wall at a distance of about 4 feet or 5 feet from the ground, so as to catch the eye easily. Some may object to having the labels made too conspicuous on the walls. In this case pieces of lead with the name of the tree impressed upon them answer well, and will last for many years. But on standards, bushes, or pyramids the labels should be suspended from the trees, so that the young gardeners may acquire a knowledge of the sorts grown, as when nailing and pruning they cannot but notice the difference between the sorts in habit of growth; also during the summer, when working amongst the trees, they have an excellent opportunity of comparing the different varieties as regards the leaves and the fruits. Besides having the trees carefully labelled, many gardeners write out a list of their fruit trees and number them, but here we adopt what I consider a very good plan, *i. e.*, draw a plan of the garden or orchard and make a dot for each fruit tree and number it; then write a list of the trees, with their names and numbers corresponding with the plan in a book. When this practice is adopted there is no trouble in finding the name of any particular tree should it happen to lose its label. C. COLLINS.

Howick.

Shading fruit houses.—Some of the houses here are glazed with inferior glass, and in these plants are very liable to injury by scorching, unless shaded much more than is necessary with good glass; and in vineries the greatest care in ventilating will not prevent scorching. I had, therefore, decided to put on a light shading this summer, but if the result is the same as in the case described by Mr. Coleman, it will be worse than the scorching. I should, therefore, be glad to know if any other readers of THE GARDEN have had any experience in shading Vines, especially with fixed shading, and if so, will they kindly state in these columns what result? W. CRANE, *Ballywalter Park, Co. Down.*

Two good Apples.—We are now using Flanders Pippin and Northern Greening for culinary purposes, and can strongly recommend them to cultivators, as they are sound, plump, and as sharp in flavour as they were at Christmas. This latter quality is, in my opinion, the point which should receive first consideration in making a selection for late use. Given a first-rate fruit-room, the keeping of Apples for some months beyond their allotted period is no difficult matter, but unless they retain their brisk flavour they are of little value. Flanders Pippin, when cooked, changes to a rich amber colour; the pulp retains its bulk, and for this reason is well adapted for all pastry purposes. The flavour is delicious, and now, even the middle of April, the juice is brisk and lively. The tree is hardy, a fairly good bearer, and deserves extensive cultivation.—W. C.

SHORT NOTES.—FRUIT.

Pear Pierre Joigneux.—This is said to be a most vigorous Pear, a large yellow fruit, with melting, juicy, sweet flesh; ripe from September to November.

Early Grape Gamai de Juillet.—This Grape was introduced by Messrs. Ballet, of Troyes. In that part of France it is said to ripen in the open air in July. It is a free bearer and has a good flavour.

Pear Charles Cocnee.—This Pear is said to be a very fertile kind, and excellent as a late dessert fruit. Fine specimens were sent by Messrs. Ballet, of Troyes, to one of the April meetings of the National Horticultural Society of France.

Vine leaves diseased.—I wish to ask your opinion or any of your contributors as to the Vine leaves sent. They are from young Vines two years planted, and now showing fruit and fine canes. Can it be the dreaded Phylloxera? I have read of it and the symptoms, but I never saw the insect. Can anything be done with it at this stage? The Vine borders are fresh made and well drained, and composed

of clean loam, old lime and mortar rubbish, and a few half-inch bones.—H. MARRIS, *St. Andrew's, Bridgwater.*
* Your Vine leaves are covered with green excrescences that form on the back of the leaves, a sort of extravasation through the skin of the leaf. They are injurious to the leaves, no doubt. This disease may be caused by a close, t. o warm atmosphere saturated with moisture. Consult Barron's "Vines and Vine Culture."—Ed.

MORE WALL AND HOUSE PEACHES.

YES, this is what is wanted. I care not to pit one against the other; we really want more of both. For a good many years Grapes have been monopolising more than their due share of space indoors, and Peaches spreading more widely over the walls in the open. Both are kings among fruit; but if these deserve regal praise and honour, Peaches and Nectarines must rank as emperors. Like Mr. Coleman, I should hesitate to affirm whether out-of-door or indoor Peaches are best. Judged by the eye, indoor Peaches would mostly be preferred; by the palate, out-of-door fruit would rank first. Out-of-door crops are, of course, somewhat more precarious. Climate comes in as a disturbing factor of great force in the open air. But climate is an old enemy, and we ought to know pretty well by this time how to meet and vanquish it. And we do. It is astonishing how successful the wary cultivator is in obtaining an annual crop of Peaches from the open wall. Of course, there are exceptional seasons now and then when the major portion of our hardy fruits is destroyed by spring frosts. But even in these exceptionally severe springs it is no uncommon thing to find more Peaches and Nectarines on walls than Apples, Pears, Plums, or Cherries in the open.

Neither is our climate one whit worse than it used to be, notwithstanding the laboured statistics of great authorities to the contrary. Hence, wherever Peaches have been well grown on open walls in the past, they may be as well or better grown now. And they are, where due care and skill are devoted to them. Nay, Peaches are better grown in the open air to-day in this country than they ever were before improvements of culture and of treatment have told upon them, as upon other things. Of course, poor, neglected Peach trees in abundance may be found on walls. The trees are usually labour, soil, and manure-starved. They may have grown in the same soil for half a century, and have to battle every summer with drought, starvation, and hosts of insects. When they do bear a crop of fruit, most of it is left to add sheer exhaustion to all the other evils the trees are subjected to; and then not a few such trees, on which hardly any labour and almost less skill are expended, are duly trotted forth in our journals as proofs of climatal deterioration and the impossibility of growing Peaches to perfection on open walls.

HORTUS.

THE EARLIEST STRAWBERRIES.

Ripe Strawberries are now fairly plentiful in most gardens where forcing is practised, and those who have relied upon the variety *Vicomtesse Héricart de Thury* will doubtless find there are none to surpass it at this time of the year. Earlier sorts there are, notably the *Princess of Prussia*, and it may be that larger fruited varieties will also be shortly available, including *La Grosse Sucrée* and *Sir J. Paxton*, but *Vicomtesse* is the best in point of quality, and it is also of excellent colour and firm. It sets readily in heat, and attains its full flavour in a forcing house, which is more than can be said of any other variety that I am acquainted with. It may not be so generally known that it is of a more accommodating disposition than most other sorts. It is rarely found in a perfect state of rest, and those plants wintered in cold frames, or protected in any way, are nearly always active at the roots, and can soon be excited into flowering. This habit of growth renders it possible to lift young plants from the open ground and force them at once. In December last we potted up a number of young plants from an open border, and these, being plunged in a bed of leaves that had been for some time previously placed in a heated pit, soon commenced rooting strongly, plenty of bloom following in due

course. Before the flowers were expanded the batch of plants was transferred to shelves in a plant and Pine stove, and here they have perfected good crops of fruit, nearly equal to any I have yet seen so early in the year, on plants treated in the orthodox fashion. At other times we have potted up the *Vicomtesse* and other varieties for fruiting under glass in quantity, and to ripen in advance of the earliest outside. The preparation of a number of plants in pots suitable for forcing, or only slightly forwarding under glass, entails a considerable amount of labour, and may well deter owners of small or under-manned establishments from persevering in the practice. If warm shelves, or even sunny pits or frames, are available, and early Strawberries be in demand, there is no reason why a number of strong young plants should not be profitably potted up, or they may be transplanted to the pits and frames. They should be lifted with good balls of soil about the roots, and be firmly bedded into rich loamy soil, and kept near the glass. I do not aver that lifted plants are suitable for immediate hard forcing, but if brought on gently, new roots will soon take possession of the tempting compost, and it may be do better service than do the roots of established plants that are crowded in an impoverished handful of soil. It may not be advisable to break up a newly established bed in order to obtain plants for fruiting under glass, but one row might be spared, the produce from this perhaps being more appreciated than ten times the quantity of fruit that may be ripe when Strawberries are most plentiful. Those we lift are merely strong runners that are allowed to establish themselves in a border, the only attention they require in the autumn being in the way of thinning out and regulating. Those transplanted to frames or pits ought to be given good room, and the bunches of fruit should be lightly supported above the foliage, or it may not ripen properly. On no account should they suffer for want of water, as should once the old balls of soil become quite dry it is certain to lead to the loss of the crop. W. L.

SEASONABLE WORK AMONG FRUITS.

CUCUMBERS.

If winter fruiteders are to be kept on through the summer, cutting over, to which I have often directed attention, must still be followed up. It is not necessary to cut over a whole house or pit at one time, but individual plants most in need of relief may be taken in hand first, and when they have grown into a fruit-bearing condition others may be similarly treated until the whole house is renovated. When divested of their old leaves, and all the fruit and straggling vines have been thinned out or shortened, a sharp bottom-heat, combined with good syringing and top-dressing, will speedily restore them to a healthy and fruitful condition. If practicable, it is a good plan to remove a portion of the old top-dressing and inert compost just when the young growths are breaking, and forthwith to earth and pack them up with fresh, light turf, charcoal, or rough pieces of old lime rubble. The bottom-heat being right, a few days' careful attention to shading will favour their complete recovery, when more tepid liquid may be given to the hills, airing, and the usual treatment may be resumed. The rapid decline in hard-forced plants is generally due to over-cropping and insect pests, including red spider, thrips, and green fly, but complete relief from their load of fruit followed by an extra supply of wholesome food corrects the first, and the facilities which thinning out offer for cleansing, not only the foliage, but the house, place the latter in an untenable position. These remarks apply to plants that have been overworked, but whose condition otherwise is sound, and these, I say advisably, may be kept in bearing throughout the season, or certainly until such time as spring-planted houses and pits come into bearing.

Spring-sown plants growing in well-appointed pits will now be making rapid progress, and provided they have plenty of room their management will be extremely simple. The main points are plentiful supplies of water both to the roots and through the syringe, a tropical temperature ranging

from 70° at night to 85° by day, ventilation when air can be admitted without creating a draught, and scrupulous cleanliness. The great mistake which many whose space is limited fall into is overcrowding, for no sooner are the plants fairly started than they begin to overlap, when the knife is introduced and canker follows. To such persons I would say, cut out every alternate plant, allow those retained to extend, pinch the laterals at the first joint beyond the fruit, and avoid the use of animal manure, as stimulants in a liquid form can be applied when needful.

Frame Cucumbers.—Although a great number of gardeners have given up growing Cucumbers in frames, as they can produce them quicker and cheaper in hot-water pits, it does not follow that the system must or will become obsolete. Indeed, many people in small places must either depend upon fermenting material, or dispense with a continuous supply of Cucumbers. I have seen good fruit cut from manure frames on the 9th of March, but each plant required incessant care and attention. Those days, thanks to hot-water pipes, have gone by, but for all this I should be sorry to see summer culture in frames done away with, the more so as the well-managed frame, even in large gardens, forms a most excellent nursery for supplying houses with healthy plants of Cucumbers and Melons. The best time to commence is early in April, as the most inclement part of the spring has then passed away before they come into bearing. Moreover, with care and attention to coverings and linings, the conditions under which the plants are grown favour a vigorous and fruitful state throughout the season.

Beds.—As half the battle depends upon the proper manufacture of the bed, the greatest care should be devoted to the fermenting and preparation of the materials. When fit for use the beds cannot be made too firm, as beating and treading in a great measure prevent violent fermentation. The situation for the bed should be dry at the base, well sheltered from cold wind, but open to the sun and convenient. Many growers are obliged to use stable manure pure and simple, but having plenty of Oak leaves I always use them with the manure in equal proportions. The frames, clean and sound, are put on at once, and as soon as the heat has declined to 90° the bed is again made firm and level, sods of fresh turf, Grass side downward, are placed upon the surface, and it is then ready for the

Compost.—This consists of turf from the igneous hills, and being deficient in lime, burnt garden refuse and old lime rubble are rather freely added. A narrow ridge is then formed along the centre of the frame, and this time we wait for the heat to ascend before we proceed with planting. Young plants from single seeds sown in 4-inch pots or small pieces of turf are then turned out from 2 feet to 3 feet apart, and allowed to take to the soil before we pinch them. Some pinch before they plant, but by planting very young and allowing the roots to get established the vines start well and proceed without further check. When two-thirds of their allotted space is covered, these vines in their turn are pinched, and in a few days fruit-bearing laterals furnish the centre of the frame. More compost, little and often, and previously warmed, but innocent of manure, is added as the roots show on the extremities of the hills, and into this the joints are firmly pegged as growth proceeds. By adopting this old-fashioned plan every joint throws out roots, and not only becomes a separate plant or capable of being separated, but the numerous roots speedily take possession of the soil, and fruit-bearing can be commenced and supported at a very early stage. From this time forward culture is simple enough, and may be summed up in a few words. Warmth, dry, heat and moisture, being imperative, we never discontinue matting at night the summer through, and periodical turning keeps the linings in a state of steady fermentation. A chink of air at night is the safety-valve against steam and impure air; but the wedges are withdrawn when we uncover in the morning, and fresh air is admitted when the temperature begins to rise. With slight fluctuations, which cannot be avoided in frames, 80° to 85° is the

aim until closing time, which ranges from 2 p.m. in the spring to 4 p.m. in the hottest part of the summer. Some are afraid to close thus early, but there is no danger, provided the plants and bed are thoroughly syringed and the frame is kept full of vapour. When the plants come into bearing we give them plentiful supplies of water, tinged with liquid or soot water, and manipulate twice a week. The best time to perform this work is immediately after the turn of the day, as the lights can then be closed with a nice overhead watering, when the temperature soon rises to the maximum. Space being limited, all laterals are pinched at the first joint beyond the fruit, and the latter is, or should be cut rather under full size. If grown quickly, frame Cucumbers, although not so clean and handsome, are quite equal to house fruit; whilst the mode of culture, without the aid of dry fire-heat, renders them almost exempt from the ordinary run of insects.

MELONS.

These, like Cucumbers, by those who do not begrudge the time and labour, may also be grown, and grown well in frames without the assistance of fire heat. The latter, it is hardly necessary to say, is a powerful aid, but those who cannot command it must fall back upon methods practised by the past generation or do without Melons. The month of April is a favourable time for making up the beds precisely as has just been advised for Cucumbers, but reveling as they do in a high temperature the succeeding month answers better. Many people run away with the idea that the Melon will grow in a swamp, and so it will through the early stages, but once the fruit has attained its full size, the high and dry temperature of Persia is absolutely necessary to the production of rich flavour. Where the heat in these beds has subsided and the surface has been covered with sods of stiff, calcareous turf, the compost, also heavy, should be thrown loosely in to get warm. Meantime, two boards, 12 inches to 18 inches in width and the length of the frame, should be set up on edge to form a centre compartment not more than 2 feet wide along the centre. Within this compartment very small cones are firmly built with a portion of the compost, and a single plant is turned out upon each centre. Like the Cucumbers, I prefer using very young plants as soon as they have made one rough leaf, as we then avoid a pot-bound ball, and they have time to take hold of the soil before we pinch for the vines intended to form the main ribs. If one plant only is placed in the centre of each light, four vines, one running to each corner, form the proper complement, whilst double the number of plants can be pinched earlier, as two breaks from each will be found sufficient. When these begin to elongate and white roots creep through the sides of the hills more compost is placed round them, but the final earthing up is deferred until the vines are pinched for the production of fruit-bearing laterals. The remainder of the space is then filled in with pure loam and lime rubble, which cannot be too firmly rammed, especially if lighter than the compost recommended for house Melons. Plenty of heat, moderate ventilation, an abundance of water and atmospheric moisture must now be made the cardinal points, and the better to secure these the linings and night covering must not be neglected. Under high tropical treatment every lateral will produce a female flower, which must be carefully fertilised from day to day until a full crop is secured, and the better to ensure a good "set" syringing and root-watering for a short time may be discontinued. Space being limited, all these laterals must be closely pinched at the first joint beyond the fruit; others at the first joint from the main vines, otherwise the frame will soon become crowded with useless spray to the detriment of the main foliage and fruit, if not the plants themselves, as overcrowding is one of the common causes of canker. I may observe that each plant should be slightly higher than the general level of the bed, as it is not wise to earth up the stems, neither should they be saturated with water. As to training, that is a matter which the grower must decide. Some fill in the back and front spaces with rough

birch or pea sticks to keep the vines a proper distance from the glass, but the best and cheapest contrivance in the long run is a set of portable trellises made of rough laths, for dropping in before the vines begin to run. Upon these they can be neatly trained, and the fruit can be elevated well up to the sun and out of the reach of slugs and other midnight marauders. Unlike hothouse especially pot plants, which sometimes give way under heavy cropping, frame Melons upon manure beds often gain strength in spite of their load, but this disposition to produce laterals must be kept in check by constant pinching to one joint and the careful preservation of every old leaf.

Insects and diseases.—The most prevalent insects are green fly and red spider, but these are not nearly so troublesome in well managed frames as in houses, the moist atmosphere charged with ammonia being antagonistic to them. Still, the plants are always liable to attack, and prevention being better than cure, the weekly puff from Bloxham's patent fumigating machine introduced through a hole bored in the front of the frame will keep fly away. Although very light smoking answers, the frame the following morning should be aired early and slightly shaded from bright sun until the time arrives for syringing. The syringe is, of course, the best implement that can be used against spiders, but the collars of the plants and the vines being slightly elevated, an occasional flooding with warm diluted liquid whilst feeding the swelling fruit will render their position untenable. The only disease to be feared is canker, and this can be checked by rubbing the parts affected with quicklime and sulphur. The most common cause of this disease is want of heat, a too moist, dank atmosphere, crowding about the collars of the plants, and the removal of or injury to the main foliage. A man cannot stand against a subtle enemy in the dark, but having pointed out the predisposing conditions, the fault must be his own if he allows canker to interfere with frame culture.

W. C.

GARDEN FLORA.

PLATE 592.

OXYTROPIS AND PRICKLY THRIFT.
(WITH PLATE OF O. LAMBERTI AND A. GLUMACEUM.*)

THE genus *Oxytropis* is a very large one, containing something like 100 species, and inhabiting mountain regions in Europe, Asia, and North America, and ranging in the colour of their flowers from violet-purple, rose, yellow, and in some varieties often white. A few are natives of our own country, and these we often see cultivated in our gardens. Being true alpine in their habit of growth, they are most suitable plants for the rock garden, and even the border, when the situation is rendered of a rocky nature by the addition of stones or brick refuse. They seem to thrive best on dryish positions, and we find them more sturdy and floriferous when exposed to the full rays of the sun. The soil in which they are grown should be light and porous, and the roots should have free scope to go downwards, as they often do to a considerable depth. They are increased by seeds or division, the former being by far the best and in the end the most satisfactory. Besides those enumerated, there are in cultivation *O. foetida*, *sulphurea*, *lapponica*, *campestris*, *ochroleuca*, &c.; all are worthy of attention, and are equally beautiful on the rockwork.

O. CYANEA.—With the exception of *O. Lamberti*, none of the others which I have seen as yet equal this handsome species. It has a large, woody root-stock forming many crowns, with stems not quite an inch in height; leaves medium-sized, with small, silky leaflets. The flowers are produced in clusters

* Drawn for THE GARDEN by the late Noel Humphreys in the York Nurseries, and printed by G. Sereyans.

on numerous slender stems, very large in proportion to the size of the plant, deep purple and very striking; the pods are large, inflated, and generally produced in abundance, the flower-heads elongating to a spike when the seeds are ripening. Besides being useful for the rockery or border it makes a most charming little pot plant, and never fails to flower in June and July. A native of Zermatt, Valais, &c.

O. LAMBERTI.—This is the Loco weed of the Americans, and is without doubt the most charming, though perhaps the most variable, of all the species at present known in cultivation. The prevalent colour of the flowers appears to be sky or deep blue, though it varies through all the tints of purple, rose, and yellow, and is also found of a pure white. C. A. Geyer, in a note, says that it is not unusual to meet with it having flowers yellow, rose colour, often white, or with the banner violet-tipped. A plant with such an extreme variation should be a favourite in gardens, especially when its habit and manner of growth suit it so well for rockery cultivation. Though the worthiest and certainly the showiest of the Oxytropis, we have rarely seen it in gardens, unless, indeed, those where only the choicest kinds are grown. This is the more to be wondered at, as the plant is a robust grower, easy to keep in health on the rockery, and increases perhaps faster than any of the others. It stands almost alone among its contemporaries with the long flower-spike, as may be seen in the coloured illustration, the other species generally having round or globose heads of flowers, few elongating to any length, and none to such an extent as this. The leaves, too, even apart from the rare beauty of the flowers, are at all times graceful, of a lively fresh green, showing most prettily in the dense tufts in which it always grows. The pods are also beautiful, smooth, shiny black, and when produced in quantity a source of great interest. It is abundant on the high plains and on the mountains from British America to Mexico, flowering with us in May and June. Introduced about 1819 by Mr. Lambert, whose name it bears.

O. MONTANA is also a charming little species with branched flower-stems in the stronger growing plants; the flower-heads more or less round, deep purple, and very handsome when well grown; the pods are inflated, giving the plant a very striking appearance when in fruit. Alps above Moritz, Tarasp, Grisons, &c.; flowering June and July.

O. PILOSA.—A robust and striking plant growing from 6 inches to 1 foot high; the whole stem elongated, and the flowers on longish stalks, produced from the axils of the leaves, and somewhat resembling those of *O. Lambertii*. Each stem produces from ten to twelve flower-heads 2 inches to 3 inches high, carrying numerous large yellow flowers; leaflets larger and longer than in most of the others, narrow, blunt, and entirely covered, as well as the stem, with long silky hairs. Botzen, Tyrol, &c. June and July.

O. PYRENAICA is a somewhat dwarf species with leaves composed of from twelve to twenty leaflets, concave, and covered with silky hairs. The stems are very short, scarcely rising above the ground, and when very robust rarely exceeding a few inches in height; flowers borne in round heads, each containing from six to fifteen flowers, purplish lilac, and very striking when produced in quantity. Native of the Pyrenees; flowering in early summer.

O. URALENSIS (the Stud flower or purple Oxytropis) is an elegant little plant, rarely exceeding 6 inches in height, and an excellent subject for either the rockery or the border. In the latter position, raised on stones or little mounds, it makes a brave show. On the rockery, where it can get plenty of sunlight, it is beautiful, and when in robust health almost hides the leaves in a profusion of its purple flowers. It has a stout, woolly root-stock; the leaves 2 inches to 4 inches long, and covered with an abundance of soft, silky hairs. The heads contain from six to ten bright purple flowers densely packed. It flowers from the end of May to July, and is a native of dry and rocky pastures in Scotland and Northern Europe. *O. Halleri* is a synonym, under which it is often found in gardens.

ACANTHOLIMONS.

Although there are not more than about three or four of these lovely Statice-like-flowered plants in cultivation at the present time, the number of species known amounts to something like sixty-one, according to Boissier, and Bunge says seventy-four. They are to a large extent, if not wholly, Asiatic, and it is to be regretted that we do not possess a larger number in our gardens, seeing how well the districts where many of them are said to be found have been explored by botanists of late years. The few we already have are quite a unique class of plants among our other alpinists, flowering all through the summer in such profusion as to make them desiderata of every garden, however small, where alpinists are grown. They affect dry rather than damp situations, and to see large plants flowering in the full blaze of the sun is a sight never to be forgotten. Our soil is well filled with broken bricks, &c., and we find this a good medium, as their health testifies; the centre is elevated, and it is a good plan where possible to plant them so that they may overhang clefts or ledges. The species most common in gardens is that figured in the accompanying coloured plate; it is the most beautiful I have yet seen, and is certainly by far the most floriferous. It is a dwarf growing plant, rarely more than a few inches in height, with crowded, short Grass-like foliage, the leaves stiff and armed with sharp spines. The annual shoots bear a tuft of closely imbricated, spreading, and recurved leaves, the older ones generally withering as the growing point advances, which it does very rapidly, the whole quickly forming large tufts of a very pretty appearance. The flower-stems are generally two or three times longer than the leaves, and bear a distichous spike of numerous and charming large rose-coloured flowers. It continues a considerable time in bloom, and is perfectly hardy in the neighbourhood of London, and does not seem to be affected in the least by the smoke. It may be propagated freely from cuttings or layers, simply singling the branches and notching and pegging down as many as may be required. When increased by cuttings they should be placed until rooted in a moderate heat, kept close, and gradually hardened off as they become established. It flowers in June, July, and August, and was cultivated about London as early as 1840. Native of Armenia. Synonym, *Statice Ararati*.

A. ACEROSUM is a rare species, forming dense cushions of stiff leaves, glaucous, and armed with sharp points; it is, however, rather a shy flowerer; flower not so large as the above; rose. July and August. Anatolia, Tauria, &c.

A. ANDROSACEUM is a synonym of *Statice Echinus*, and is nearly allied to the above. *A. Kotschyi*, a handsome species with white flowers, and *A. melananthum* and *A. venustum* are also desirable for rockeries or borders. D. K.

Calcectasia cynea.—This plant is a native of South Australia, and belongs to the Rush family (Juncaceae), a group of plants which is not remarkable for showy flowers. The plant in question is a branching shrub, with small, subulate, sheathing leaves, and large, starry flowers, with a flat, six-lobed, spreading limb of a shining, dazzling blue, with conspicuous yellow stamens; these flowers are produced on short, lateral branches forming a raceme some 9 inches long, the blooms all expanded at the same time. This plant has not yet been introduced to this country in a living state, although the Messrs. Rollisson imported seeds upon several occasions, but never succeeded in growing them; but, judging from the great numbers of Australian and Cape plants which are now flowering with Messrs. Low in their nursery at Enfield, this class of plants would appear to be again coming into

favour with the general public, and the *Calcectasia cynea*, if introduced, would prove a stimulus to the cultivation of these once popular ornaments of our greenhouses.—G.

CHRYSANTHEMUMS.

E. MOLYNEUX.

Now that the weather has so much improved, plants are gaining ground rapidly both in size and healthy character. A want of sun and a continuation of cold easterly winds have tended to make some collections present a sickly appearance. Plants grown for any purpose should now be in cold frames, as being more conducive to that still, short-jointed growth so necessary to the highest success. Abundance of air should be given to them upon all favourable opportunities, although avoiding direct draughts as much as possible by tilting the lights on the opposite side to that from which the wind blows. Careful attention must now be paid to watering, never allowing any of those plants growing in small pots which have not yet had the necessary shifts into larger ones to suffer for want of it. These, owing to the mass of roots they possess, soon become dry, and if allowed to flag for want of water they are apt to lose some of their bottom leaves, which renders the plants unsightly and interferes considerably with their future welfare. Tepid water should also be used, as cold water applied to the roots at this early stage oftentimes renders them sickly in appearance. Continue the potting of all plants in their various stages as required, never allowing any to become pot-bound for any length of time. If possible, those newly potted should be kept a little closer for a time, until the roots have taken hold of the new soil. See that none are overcrowded, but thin out as soon as the leaves touch each other. Those plants intended for the production of large blooms will now require support, as some of the weaker-growing sorts are apt to become bent or broken down by the weight of foliage. This is better effected by attaching a small stake to each. Continue the stopping of the branches of such plants as are grown for specimens, pompous and single varieties included.

SOIL FOR CHRYSANTHEMUMS.

THE preparation of the soil for the final potting into flowering pots of a large collection of Chrysanthemums, no matter for what purpose they are intended, entails a certain amount of time and forethought, particularly when the necessary ingredients are not at hand. It is better to look ahead in this, as in all other matters of detail. Successful results depend much upon the soil used; therefore, any preparations now made will be found an advantage, such as placing soil, &c., under cover, to be sufficiently dry when used; the ordering of bones, or whatever artificial manure is thought best. Soils of a complex nature are often recommended, as if elaborate mixtures necessarily possess extraordinary virtues. Good soil is important, but it is only one element in the case. The effects of the best compost that can possibly be obtained may be completely nullified by errors in watering and general management. The after treatment of the plants is the all-important part to be studied, as these plants have such a short season of growth and so much has to be done in a few months, that they must have every attention. To this end the composition of the soil is not of so much importance as after feeding. The soil, then, while it contains food, must be regarded as a store for additional food which may be required, and given from time to time. It is a mistake to suppose that soil must be prepared and stacked for six or twelve months previous to using it. No absolute rule can be laid down as to what mixture is the best, as soils differ so much in their nature in different parts of the country. I will endeavour to make this part as

clear as I can to suit various localities, just describing the different ingredients used.

Loam, as it is called, is composed of the top spit of an old pasture, cut according to the depth of the fibrous roots of the Grass, in some places 3 inches deep, in others 1½ inches, according to the time the pasture has been laid down. It should be cut some time previous to using, just long enough for the Grass to decay, but preserving the fibrous roots intact. If the turf is light in character and cut from where the land is of a sandy nature, ground oyster shells should be added; but if the turf is taken from a district where chalk and limestone abound, add more charcoal and wood ashes in lieu of oyster shells. Charcoal is of great assistance in keeping the soil in the pots porous and acting as a store-house for ammonia. If the turf is of a retentive character, remove the fine soil, as this prevents a quick passage of the water when applied copiously. Those growers having a rather light soil at disposal are much more favoured than those who have to depend upon soil which is of a clayey nature. When light soil is used the moisture escapes from it quickly; consequently, feeding can be more frequently and safely carried out than in the case of soils of a retentive nature.

Manure is the ingredient second in importance, and must be applied in some form or other. Well decomposed cow manure is often recommended. This is wrong, because what beneficial properties can there possibly be in manure entirely decomposed. It is the same with decomposed botch manure. The violent heat of the mass during fermentation dissipated the ammonia, which, above all things, should be preserved for the benefit of the plants. I do not approve of cow manure in any shape. I consider it most injurious when used with soil of a heavy character, it being too close in nature and far too binding. The best manure is that prepared as if for a Mushroom bed, shaking out more of the straw than would be required for the growth of Mushrooms, and retaining little else but the droppings. It is thus sweetened whilst most of the ammonia is retained. This is the best manure to employ for soils, both of a heavy and a light character. Finely ground bones are better than half-inch bones, as the latter do not give out their manurial properties sufficiently during the short period in which the plants make their final growth and bloom. Dissolved bones are also beneficial when used in proper quantities. Soot is a powerful agent when cautiously applied, but when used excessively it has a most injurious effect upon the plants. I have seen plants which have lost all their leaves and others presenting a very sickly appearance through the misuse of soot. Lime in a quick state is useful for the destruction of worms, and every means should be taken to destroy these. The best time to add lime is when the soil is being prepared for potting; a handful occasionally during the operation is all that is required. The sand used should be coarse and gritty; that which is fine and liable to bind the other materials should be avoided. Clean, coarse silver sand is the best. Leaf mould in a half decayed state is an excellent ingredient to add, more especially in the case of heavy retentive soils, as it is of great assistance in keeping the whole mass porous. I will now give as near as I can the necessary quantity of the materials described. To be precise I purpose taking the two cases in hand—heavy and light soils—giving the details required in each composition. Taking the former kind first, I would advise as follows: Three parts of fibry loam broken up roughly, taking out the fine soil, one part of horse manure, one part of half-decayed leaves, one part of coarse silver sand, one-fourth part of fine ground bones, and the same quantity of dissolved bones, one part of charcoal and wood ashes, the former to be used in a rough state, about the size of small walnuts. Add a 6-inch potful of soot to every 1 bushels of soil. The many kinds of artificial manures are all much better used as a top dressing than for mixing with the soil. Where the loam is light in texture, use four parts as fibry as possible, adding two parts of horse manure, one part of leaf soil, half a part of coarse silver sand, the same quantity of ground oyster shells, half a

part each of finely crushed and dissolved bones, and the same quantity of soot as advised for the heavier soil. Thoroughly incorporate the various parts, using all as roughly as possible. The action of mixing reduces the parts considerably; therefore if the turfy loam and other ingredients be chopped small at first, the mass becomes too fine through frequent turnings. E. M.

KITCHEN GARDEN.

W. WILDSMITH.

RENOVATING A GARDEN BY SUBSOILING.

SOME years ago I well remember attention being called to a system of subsoiling and the good results that sprang from it, then carried out at Woodstock Park, Ireland, by the late Mr. Charles McDonald. Not long since I happened to meet with an old gardener in a country district who had been instrumental in converting an old and worn-out garden into a new one by the process of subsoiling or something similar.

The garden that underwent this transformation was probably 300 years old, and when an old mansion was pulled down and a new one re-built in a different position it was continued as an orchard garden simply, and the new garden being made at a considerable distance from the old one, very little manure found its way to the latter. Everything that it could yield was taken away.

When my informant first saw the old garden it appeared to him a remarkable sight; the many generations of old fruit trees—some of them decayed to the ground—were covered with masses of Lichen and Moss; the smaller branches of the Apple trees were hardly discernible for the Lichens, and it was startling to hear "It used to be a good fruit garden." In looking round for the cause of such phenomena, the tall forest trees on three sides were credited with assisting in such a development of Lichen growth, but there was something that indicated excessive moisture in the soil, and draining was at once commenced, and the digging of the trenches for the drains revealed the state of matters under ground. The natural formation of the garden was found to be a cold clay slate, with an iron pan running at from 1 foot to 2 feet from the surface, rarely exceeding 1 foot in thickness, and under it there was about 3 feet of the loose clay slate, and under that a rocky bottom. The old garden lies on a slope with a fall of nearly 1 foot in 10 feet, and the excess of rain water from a range of higher ground filtered over the pan all the winter. After matured deliberation, the conclusion came to was that no substantial renovation could be achieved without breaking up the inveterate pan, which was so hard that the pick would not break it up, and crow-bars and powder had to be employed. In proceeding with the work one object was kept in view—namely, the production of a new soil to replace the surface soil, which was worn to a black, brittle substance about the consistency of coal ashes. A first trench of 35 yards long and 4 yards wide was made to the depth of 4 feet; as the work proceeded, the cleanest of the small stones were strewn equally over the bottom of the trench in the form of a drain; over these stones were placed small branches of Laurel, &c., to the depth of about a foot, and over the branches a quantity of rubbish and vegetable matter; over this was thrown the top soil of the next trench, and the bottom clay brought to the surface; the depth of each trench was increased until the last was made about 6 feet in depth. When this work was begun, a system of burning part of the clay was put in operation, and was continued for some time after, as opportunity served, for the purpose of supplying potash and other fresh salts to the ground. This, then, is the history of subsoiling the old garden.

Now for the results. It should be stated that the very worst of the old fruit trees were destroyed; some were allowed to stand, some transplanted. The appearance of the trees before the commencement of the work has been described; except a few scraggy Cabbages, no other vegetable would hold in the soil, and such things as Spinach and Parsley could never be gathered fit for use. But afterwards

good crops of vegetables were obtained, and no manure save the burnt material was placed upon the ground for a space of something like six years. Previous to the draining there was rarely one-third of the Apples on the best of the trees fit to keep, or worth putting into the fruit room; but afterwards fair crops of clean fruit were grown. The crops improved in course of time, and the ground became in good condition for planting young fruit trees, which was a necessity.

Here, then, is a proof of the truth of the proposition that soils generally are of inexhaustible fertility if properly turned up and mixed. R. D.

HARDY BROCCOLI.

OUR friend, Mr. Gilbert, has great faith in the crowbar, and never loses an opportunity of extolling its merits for planting out seedlings of various kinds, and in THE GARDEN (p. 309) he seems to imply that if gardeners would only go in for crowbar-planting, there would be plenty of Broccoli in all kinds of seasons. Now, I cannot give much information about this kind of planting, as not one in a hundred of our market growers has such an instrument as a crowbar in their list of garden tools, but, nevertheless, they grow Broccoli to perfection in open fields. And here I can fully agree with Mr. Gilbert on the value of a firm and not over-rich root-ruin for Broccoli, and, above all, an open, sunny aspect, so that the growth may be hard and well matured. It is simply impossible to get such stocky, short-legged plants in close-walled-in gardens, frequently overshadowed by fruit trees, as one gets in the open fields of the market grower, as the private garden too often has to do duty as orchard, flower garden, and kitchen garden combined; while market growers, as a rule, find it best to do one thing well.

Now, with us Broccoli for spring use is not sown or planted nearly so soon as in more northern counties; in fact, when the winter season sets in, a good many of the Broccoli fields look very thinly covered with foliage, as the plants look only half grown and stand out quite clear of each other; but by keeping the surface soil stirred the plants keep on growing gently through the entire winter, unless in such severe seasons as the past, when the soil is hard frozen for weeks. The soil is simply ploughed, and is therefore very firm but a short depth below the surface, and to this fact alone the safety of the field crops of Broccoli is largely due, as even in this comparatively favoured locality the garden crops have suffered heavily. I think we should be doing far more good with Broccoli and many other garden products if we devoted more time to growing the sorts we have got, well, rather than in always hankering after something new; for the idea of any Broccoli of the true white kind standing such a frost as we have had registered in some parts of the kingdom during the past winter, when strongly grown, appears a hopeless task, as they are much harder when treated to full exposure and a rather poor soil. And that good spring Broccoli can be grown in this way, and be quite safe from anything but a frost that gets dangerously close to zero, can be easily verified. Winter or very early spring Broccoli that needs to be fully grown before winter sets in, must, in my opinion, be always liable to great losses from sudden visitations of severe frost. If we have many more winters like the past, I shall predict that the Purple Sprouting Broccoli will be again in great request, as, unless we had put out an extra stock of it last year, our supply of good green vegetables would have been very limited indeed.—J. GROOM, *Gosport*.

— Such is the heading of a short paragraph in your issue of THE GARDEN, April 2 (p. 309). Have your correspondents, "One who Smells Them" and Mr. Record, who also wrote on the subject the previous week (p. 286), ever given Vetch's Model a trial? I have now grown this late spring variety several years, and have never known it fail. With me here in the north it stands the winter well, and I am speaking of two years' experience of it here—both bad winters for Broccoli. The winter before last it was the only one of many varieties grown that stood the winter, and this last season I have

not lost 5 per cent. of my plants. It is a stiff, short-legged variety, and does not make such thick, pithy stems as Broccoli generally does, and one which, if not sown too early and planted on good firm soil, will not fail to stand the winter and give every satisfaction as to quality. Whilst writing on this subject I would like to emphasise some remarks in Mr. Gilbert's letter of April 2. One is, that Broccoli is often sown too early. Here I find the first week in May quite early enough. As to planting on good firm soil, I am quite at one with him, nothing, in my opinion, being so injurious to Broccoli as planting on recently dug or manured ground, conducing as it does to thick, pithy, watery stems, which the first severe frosts will destroy.

H. E. GRIBBLE, *Wynward Park, Stockton-on-Tees.*

It will be good news to most gardeners to read in THE GARDEN (p. 309) that "a hardy Broccoli is not wanted, because we have plenty." There is not one pure Broccoli in existence that is perfectly hardy either at Buzby or anywhere else in England where severe frosts are occasionally experienced, and when the editor asked for a hardy Broccoli he expressed a general-felt want that has been long experienced. Purple Sprouting, Eclipse, and Carter's Champion types are the nearest approaches to a hardy Broccoli we possess, but they are not quite hardy, and the Purple Sprouting, though a good sort and much esteemed by gardeners on account of its productivity, is not liked on account of its colour. If a hardy Broccoli is not wanted, why, pray, has Mr. Gilbert been preaching up his *cross-heads* of that ilk for years on the plea of their hardiness! "Want men to grow Broccoli!" Why, I could produce him cuttings by the score that grow Broccoli of the best quality, and as long as it can be had, Mr. Gilbert's way of making Broccoli stand severe winters must be new even to him, for it is not so long since he sent me heads of his Cabbage Broccoli to cook that he said *were the only vegetables of the kind alive in his garden then*, all the others having been killed by frost, and those sent, though good, were *Cabbages, not Broccoli* at all. J. S. W.

I note Mr. Gilbert's letter on the above in THE GARDEN (p. 309). It only, however, states about half the truth. As one of the first cultivators to insist on a hard soil for Broccoli I endorse all he says of the hardening influence of this on the plants. A hard regimen, arising either from lack of food or looseness of texture, produces a sturdy if not a stunted growth, and thus presents a smaller area to the cold and stronger power of resistance than larger or more lanky plants. A good crown of leaves is also a capital protection for Broccoli stems, but the stems are often safe enough while the crowns are frost-bitten, and sound stems are a poor consolation for rotten hearts. The value of Broccoli rests in its crown, and the frost bites that with equal impartiality whether it be within 6 inches or a yard of the ground. In fact, it not seldom seems that the nearer the ground the harder and sooner they are frozen, though of course dwarf Broccoli has a better chance of being protected with snow. However, the latter, and notably this year, has not saved the Broccoli; the majority of ours were so covered, and all but the Purple Sprouting, as in your own case, have perished. This has been the worst and most destructive winter for Broccoli ever remembered in an experience extending over forty years. Hence, with much feeling, I echo your advice to Mr. Gilbert to give us a hardier Broccoli. They would be more gladly welcomed than his Broccoli Cabbage, which will never become popular, as so many have never yet found out where and when the Cabbage ends and the Broccoli begins. As a Cabbage it is tender, luscious, sweet; but as a Broccoli, well, let us have something hardier, if possible, and with more Broccoli in it. HORTUS.

Not far from here is a large breadth of the late white Broccoli growing in an open, exposed field and in a stiff clay soil. The outer leaves, as is so generally the case, had been killed by frost, but the hearts and stems are sound. The heads will not be large, but the price may in such a season as the present help to recompens in the other direction. Inquiring as to whether this Broccoli was planted

in the hard soil on to another crop, I learnt, so far from that being the case, that it followed upon Cabbage, the soil being well manured and ploughed before planting. The planting was, however, rather later than usual, and that may have conduced to the saving of the crop. Then, again, this old kind may be hardier than are some of the newer sorts. Close by was seen the odd circumstance of about a couple of acres of dark red Wallflowers, the plants very large, but 80 per cent. of which had been killed by the frost, inflicting a very heavy loss indeed on the grower. Then adjoining these were about half an acre of also stout bushy plants, nearly the whole of which were sound. This curious case prompted inquiry, and here I found that the injured stocks were from an autumn sowing in 1885, the plants standing in the seed-bed for the winter, and being planted out in the open ground early in the following year. It is of so much importance to obtain early bloom on the Wallflower, if any profit is to be derived from its culture, that it is often striven to take time by the forelock, though not always with success, as this instance showed. The injured breadth was from a sowing made last spring, and if the plants were neither quite so large nor so early, they were at least safe and sound, and worth twice as much as the whole of the larger breadth. A. D.

MARKET SALES OF GARDEN PRODUCE.

AS most gardeners have now to turn all spare produce into money, or grow crops specially for market, very many of your readers are greatly indebted to you for your most useful and practical article on this subject. The sales that you have succeeded in establishing will no doubt prove useful, and it is high time that something were done in the matter. Some years since I was sending Gardenias to London, and had a penny apiece returned for them. My master was staying in London, and went to the same house and purchased some on one occasion, and was charged 2s. 6d. apiece for his own flowers. The private seller is nowhere as against the salesmen and shopkeepers. The latter mostly give the best prices, but the returns are not seldom slow and uncertain.

Another great grievance is the matter of empties. Useful flower boxes can hardly be had at less than 6d. or 1s. apiece. Biscuit and other boxes used to be cheaper. But now that commercial and agricultural depression have driven so many private growers into the market, all suitable boxes are bought up greedily and the prices have risen; hence the purchase of boxes really becomes a heavy first charge on produce. No matter how carefully you endorse your name and address on them, nor how particular and frequent your instructions, it is hardly possible to get your empties returned. True, after writing perhaps a dozen times, a package of empties is sent. These as often as not consist of a ponderous mass of heavy old soap or other boxes, without tops, utterly and wholly useless, and after paying 2s. or 2s. 6d. for them you discover that they are only fit for firewood, and not one of your nice handy boxes is among them. This is really a serious matter, as the bill for boxes often runs up to several pounds in the year.

I presume the difficulty arises through the selling of the produce in the sender's boxes, and the purchaser keeps them when they are good for anything. A remedy might be found by adding the price of the boxes to their contents, or by selling the contents without the boxes. The latter would probably be impracticable. Possibly the Messrs. Draper, with their great experience, might be able to solve the box problem to the satisfaction of the consignors to their Monday, Wednesday, and Friday's sales. As soon as the box problem is solved, I will contribute to them cut blooms of Niphetos and other Roses and flowers, and probably fruits.

A MARKET VICTIM.

Sea sand.—I am very suspicious about using sea sand for plants, but there is sea sand and sea sand. Had your correspondents, who recommend it for cuttings, procure it from a spot that is frequently covered by the tide, or from

those sand dunes and banks so common on some parts of the coast, and consisting of old beaches now left by the sea or blown sand-hills? I have often tasted the sand on the beach and near it, and found a great difference to exist in respect to its saltness, that from the dunes being practically saltless, while that on the beach and periodically covered by the tide was too salt for pot plants, for it is the salt that makes sea sand dangerous.—S. W.

KITCHEN GARDEN NOTES.

CARROTS. Drying north-easterly winds have been so continuous during the past fortnight, that the ground is in the best form for seed-sowing; hence, though somewhat early, we have sown the main crop of Carrots, James's Intermediate and Long Surley. The ground was deeply trenched, but no fresh manure added, having been well manured for the previous crops, Celery and early Broccoli. The early Carrots sown on a south bank are now well through the soil, and the ground being so dry, hoeing has been done between the rows with a view to destroy weeds and promote rapid growth, that there may be no break in the supply between the frame-grown Carrots and the early open-air crop.

PLANTING ASPARAGUS. Before this last spell of cold weather Asparagus had begun to show through the soil, but 8° of frost and dreadfully cold winds destroyed every bit that showed. There is plenty of underground activity, and with a genial change of weather, cutting will soon be general. As a rule, we do not care to make a new plantation till the roots have got into full activity; that is, till new stems are about an inch long. Though not this yet, but only just forming at the crowns of the plants, the conditions as to soil being favourable, we have transplanted them to form a permanent plot. The ground has been in preparation ever since the autumn, when it was trenched as deep as the sand and gravelly subsoil would admit of, two layers of the best stable manure being put in at that time and the soil left rough, that frost might have the fullest pulverising effect on it; a few weeks since a dressing of salt and soot was given, and afterwards the ground was levelled down by digging it with forks. The planting has been done in lines a yard apart, and 2 feet from plant to plant, and in trenches 6 inches deep, the plants being covered over to the ordinary ground line. If we had manure to spare we should thickly mulch the lines throughout; as it is, a little over the crown of each plant is all they are likely to get, and this is really necessary to keep the plants growing through dry weather, for watering is quite out of the question. To old plantations we have given a second dressing of soot, which is an excellent fertiliser and a sure slug preventer. A small piece of ground has been sown with Asparagus, some of which may possibly be large enough to plant out next year, but it will be two years before the bulk of the plants is ready.

DRILL.—It is now time to make the principal sowing on ground free from fresh manure and that has been deeply dug or trenched. We sow in drills from a foot to 15 inches apart, and thin out to 9 inches. Probably no other kitchen garden crops, whilst in the seedling state, are so tempting to slugs, and to guard against their depredations we scatter soot in the drills with the seeds, and also as soon as the plants emerge from the ground, and we repeat the application as often as necessary till the thinning out of the plants is done, when they are too large for the slugs to have any damaging effect on them. Dell's Crimson is our favourite variety.

FRENCH BEANS.—We have made a small first sowing on a south and well-sheltered border. Sometimes such an early sowing does well; but, as a rule, there is little gained by sowing earlier than the end of the month. Some sow in boxes in warmth, and transplant to open borders as soon as danger from frost is past, but it is a plan not to be commended. A more successful way is to sow in small 3-inch pots, about four seeds in a pot, and plant out as soon as safe without disturbing the ball. This growth goes on without check, and, barring injury from frost, a fortnight or three weeks may be gained over those sown at the earliest date in the ordinary way. Osborn's and Fulmer's Forcing for the earliest, and Canadian Wonder for general crops, are amongst the best varieties. The

two first-named may be sown in rows as near together as 2 feet, but a yard apart is none too much for the last-named, and small twiggy sticks are needed as supports, as it crops so heavily.

POTATOES.—We have completed the planting of all kinds. The distance apart of sets varying from 2 feet by 14 inches in the short-hauling kinds to 3 feet by 2 feet in the strong-growing late kinds. The early kinds planted on south borders are all up, and to prevent injury by frost we keep them well ridged up, and as soon as they get too high for this, a little long litter will be put over them each night when there are indications of frost, and be placed between the rows at all other times, or at least till all danger from frost be past, when it will be cleared away, and the ground be lightened up either by shallow forking or deep hoeing.

HERBS.—Sowings of annual kinds have been made in shallow boxes in warmth, to be presently planted out on any spare bit of ground that has a sunny exposure. The kinds now sown are Sweet and Knotted Marjoram, Borage, Basil, and Chervil; Thyme and Sage we have also sown, as we wish to replace with young plants the old ones that have got woody and crippled by the past two severe winters. Pennyroyal we have lifted, divided, and replanted, and also increased our stock of Farragon by division of the roots. Of Mint, the supply being ample, it was only necessary to clear off decayed stems and weeds and apply a fresh top-dressing of good soil.

GENERAL WORK.—To give plenty of air on all favourable occasions to Potatoes, Carrots, Lettuce, and Radishes in frames; the lights will be quite drawn off in mild, and particularly during mild, showery weather. Carrots are sown so thin, that thinning out of plants is not required, but weeding and stirring of soil between the rows is of prime importance. To plant remainder of Seakale cuttings that have been made from the roots that have been forced, and also to plant the forced Rhubarb roots after dividing them, that we may increase our stock. Thin out Spinach, stake Peas, dig out trenches for Celery, and plant out remainder of autumn-sown Onions that were too small for transplantation when the others were done a few weeks since.

W. W.

BOOKS.

THE CONSULTING ARCHITECT.*

By this rather clumsy title (not the less awkward and incorrect because it is already in use in another profession) the author of the work before us intends an architect who is called in for consultation and advice, as distinguished from one who makes a design and controls the execution of it. "The Advising Architect," one might more fitly name him. Professor Kerr does not, however, limit his book to the evident intention of its title, but expatiates over all matters that concern the architect in any capacity except that of artist. "The Architect as Man of Business" would perhaps be the best title for the volume. We have "sections" on consultation and evidence, arbitration cases, cases of structural damage, questions of easements, questions of ancient lights, questions of support, sanitary cases, leasehold questions, questions of valuation, questions of building, Building Act (London) questions, and on architects' disputes and etiquette. The book is a valuable and unique one, wide in scope and closely compacted of experience (not all of it pleasant!); altogether such as no architect can afford to dispense with, since it has become obtainable. As regards the experience, indeed here and there we detect a half-suppressed bitterness of tone, where the topic reveals to the author's mind some injustice of which he or another has been made victim by the aid of hungry and unscrupulous rivals—"cannibals," justly so named. Written by an architect for architects, "The Consulting Architect" probably does not expect any large number of readers among the general public. The final section, however, which deals at large with architects'

* "The Consulting Architect," by Robert Kerr, Architect. John Murray, London.

services, charges, practice, authority, and so forth, should be perused and considered by everyone who is likely to be concerned with architects and their works. By the greater number of people who employ an architect or "do without" one his labours and qualifications are little understood or appreciated, and will so remain; but those few who are both capable and desirous of being better informed in this respect may there find matter worthy of their contemplation.

W. SIMMONS.

TREES AND SHRUBS.

W. GOLDRING.

THE MANNA ASH.

(FRAXINUS ORNUS.)

THIS is the *Ornus europæa* or Flowering Ash of old writers, and a very handsome tree it is. Considering its great merits as an ornamental tree, it is comparatively neglected by planters at the present day, though years ago, in the tree-planting age, as we might call it, it must have been a great favourite, judging by the many grand old specimens that exist in arboreta and gardens throughout these islands. The list of the fine Flowering Ashes in this country which Loudon gave in his "Arboretum Britannicum," published fifty years ago, would be lengthened considerably were all the large trees that exist now enumerated, for there are few important gardens I have visited that I have not met with remarkable old Flowering Ashes. Old specimens, however, of this tree are not always the most valuable from an ornamental standpoint, for in maturity it is too much like the common Ash. It is when it is half grown, say about 20 feet high and very vigorous, that it is most

Cluster of bloom of Manna Ash (*Fraxinus ornus*).

remarkable as an ornamental tree, for then it has a dense head of luxuriant leafage, and produces in early summer a profusion of feathery clusters of flowers, which being almost white make the tree a conspicuous object and diffuses their fragrance widely. When old it flowers less freely, and its foliage is not so vigorous. It is, in short, a tree not to be lightly esteemed as a lawn tree or a park tree. It is only a medium-sized tree even when fully grown under the most favourable conditions, therefore is suitable for places where space is limited, but it is not advisable to plant it too near a dwelling house, as the perfume of the blossoms is sometimes overpowering. Until it reaches maturity the tree possesses, as a rule, a dense head of regular outline, and is different in aspect from any other species of *Fraxinus*. It is a tree not at all fastidious as regards soil or situation, but, like most other trees, enjoys a sheltered spot and

a deep good soil. Like all the Ashes, it is a surface-feeder, and soon exhausts the soil about it; in fact, it is what one would call a hungry tree, one that should not be planted near any

Foliage of Manna Ash (*Fraxinus ornus*).

choice or weaker growing trees or shrubs. It thrives best and looks best when planted singly, or in a group of three or four on a lawn.

CORNUS MAS.

THIS is amongst the most attractive of all deciduous shrubs just now, by reason of the still leafless branches being thickly studded with clusters of small yellow blossoms. Loudon says, concerning this *Cornus*, that as an ornamental tree the *Cornel* is valuable, not only on account of its early flowering and the fine display made by its ripe fruit, but because it is a low tree, never growing out of bounds, and one which, after it has attained the height of 10 feet or 12 feet, is of slow growth, and of very great duration. To this might also be added the desirable fact that it will succeed in almost any soil, even in light sandy places. The fruit is, when ripe, of a very bright crimson colour, but at times it does not berry freely. There is a variety of this with variegated leaves, known under the name of *elegantissima aurea*, in which the foliage is deeply margined with gold, and the young leaves, when exposed to the sun, become suffused with a pinkish tinge. Another highly ornamental species of *Cornus*, and one whose principal features stand forth more conspicuous during winter than summer, is the Dogwood (*C. alba*), the bright red bark of which forms a very attractive object when the plant is devoid of foliage. It should be planted in such a position that it will be lit up by the rays of the sun, for in winter the effect is greatly heightened thereby, especially if there is a background of Evergreens. When associated with the golden barked Willow (*Salix vitellina*) the two form a beautiful picture on a bright winter's day.

There is a variety of this (*sibirica*) less vigorous than the type, but it is one that must be by no means passed over, for the bark is of a lighter and more vivid red than that of the older kind, added to which that of the young shoots is covered with a lightish bloom, thus stamping it as very distinct. A form of this last has the leaves edged with the clearest white. This must be planted where it will not be too much roasted up during summer, as the dry hot weather is liable to injure the foliage. *C. alba* takes its title from the colour of its fruit, and is also known as *C. stolonifera*. The name of *sanguinea* is often applied to this kind, but the true *sanguinea* is a totally different plant, as the young bark is green, but the decaying leaves are bright red. The flowering Dogwood (*C. florida*) is a very handsome species, but one that is frequently seen in a by no means satisfactory condition. In the United States it takes high rank as

a beautiful flowering tree, and bears a profusion of white flowers in early spring. Another kind, which in a young state, at least, appears likely to bear out its character of being very desirable, is *C. brachypoda*, a native of Japan, and one of Messrs. Veitch's introductions from that country. It is by them described as a handsome deciduous tree, attaining a height of 30 feet, and quite unlike any other *Cornus* in cultivation.

It has an erect trunk, from which the branches grow horizontally, and the secondaries also grow in a similar manner, so that the whole branch has a tabulated appearance. The leaves are bright green above, glaucous below, and die off crimson in autumn. The flowers are produced in June, in cymes as large as those of the common Elder, but of a purer white. The remarkable habit of the tree, its handsome foliage, and the profusion of its white flowers, give it a high rank among ornamental trees for the park or landscape. Now, our specimens, though small, bear out to a certain extent the above description, and their flowering is awaited with interest. There is a variety of this in which the leaves are margined with white.

H. P.

Dwarf Furze (*Ulex nanus*).—This is not so frequently met with as the common kind, but of all

times! Those who have a fancy for more than one colour can use the rose and white-coloured to mix with the crimson. There is this further to be said in favour of the Japan Quince, that scarcely any manner of neglect can spoil its beauty. It can be easily and quickly brought into shape again. It will always retain its beauty, though it may lose its primness by neglect to be pruned. No amount of pruning, however, can ever give it that hard, solid, expressionless surface so common to evergreen hedges. The newer *Cydonia Maulei* is a similar and quite as beautiful shrub for hedges, but the flowers do not display that variety of colouring which the common Japan Quince possesses. One of the finest hedges of Maule's Quince is in Mr. Stevens' garden at Byfleet, where every season it is one of the most beautiful features of the place.—W. G.

Pyrus Maulei—This naturally assumes a neat bushy habit of growth, and as it produces a considerable number of fibrous roots it can readily be lifted from the open ground and potted up for flowering under glass. As this *Pyrus* flowers out of doors very early in the season, little more than protection from frost is necessary to have it in bloom by the beginning of March, and it will last at least a month in flower. Apart from its adaptability for indoor decoration, this is a valuable low-growing

Flowering twig of Manna Ash (*Fraxinus ornus*); full-sized flowers, detached. (See p. 354.)

the wild flowers that bloom in the autumn it is by far the brightest. In its highest state of luxuriance it does not attain more than 1 foot, and in a general way not more than 6 inches in height; it would, therefore, be just the thing for carpeting a dry sunny bank where perhaps but little else would thrive. In woodlands, in a suitable position, this little Furze should have a place, for it blooms early through the dreary and flowerless months of November and December when fairly open and mild. Now is a good time to plant both this and the common Furze, and it is the best season for sowing their seeds if large quantities of seedlings are required for future planting.—W. G.

Hedges of Cydonia—As an ornamental hedge in places where a hedge of the ordinary stamp would be objectionable there is nothing to surpass, if it equal, the Japan Quince (*Cydonia japonica*). There are numbers of deciduous plants that make pretty hedges, but the majority of them are difficult to form and troublesome to keep in good shape and order. The *Cydonia* is almost entirely free from these objections, provided only that young plants be used to start with. What a lovely sight it is when in bloom, and how picturesque at all other

shrub, for it is perfectly hardy, flowers most profusely, and at a time when it is additionally welcome, besides which the comparatively large ruddy-checked fruits form in autumn a most conspicuous feature. Its propagation is of the simplest, for suckers are produced freely enough, and though they may not be rooted when detached from the parent plant they will soon strike if stuck firmly in the open ground. Two or three of my plants pushed up a great quantity of these shoots from below the soil, and being desirous of increasing our stock, I lifted the plants, and with a knife cut off every sucker at its base. Those that were rooted I planted out, and the others were put in a couple of nursery rows, where they all rooted and have now become nice little plants. Besides this, seed-ripen in this country from which young plants can be easily raised.—T.

The Larch as a lawn tree.—Mr. W. Goldring breaks comparatively new and most useful ground in calling attention to the common Larch as an ornamental or lawn tree (p. 310). Your graceful illustration of a young European Larch on the same page gives additional force to his commendatory remarks. We have hardly any tree that is

more strikingly beautiful in all its stages. The soft green of its tender shootlets clothed with its glowing cones, so vividly described by Mr. Goldring, are hardly more beautiful than the brilliancy of its golden hues in early autumn. And yet it is so seldom ornamented with groups or single trees of Larch on lawns or in home woods. Being so generally grown as a nurse or forest tree, the Larch somehow seems to have got removed from the ornamental landscape for the very vulgar reason probably of its being thought too common, and yet we have no tree that will take its place, or provide similar forms, colours, or odours; hence it is to be hoped that Mr. Goldring's timely remarks on its unique beauty and effectiveness may lead to its more general introduction. Not a few landscapes are spoiled by impossible attempts to grow semi-tender and comparatively rare trees that might be furnished with rich arboreal beauty through the planting of such common trees as the Larch, the Scotch and Douglas Firs, the Birch, Lime, &c. May I venture to recommend to Mr. Goldring the Lady of the Wood, or Birch, in its many forms as a companion tree in the landscape to the Larch? Groups, or groves, or even single trees of Birch are at once exquisite in grace and fragrance; while the stems of the Silver Birch add a brightness and beauty to garden scenery that no other tree can impart, and yet the Birch is almost less used than the Larch in the formation of landscapes.—D. F. F.

TWO EARLY WALL SHRUBS.

CONSIDERING the extreme beauty and floriferousness of *Ribes speciosum*, the most brilliant and the best of all the flowering Currants, it is surprising it is so seldom planted on walls. Many years ago I remember being so struck with a large plant of this in flower on a farmhouse in the early spring, that I turned off the public road for some distance to verify its identity. It can hardly be surpassed in brilliancy of colouring and profusion of its graceful racemes of drooping blooms; whilst the tender Currant-like leaves, which almost run abreast with the blossoms in this fine variety, are of the softest and most pleasing hues in the early spring-time, and remain clean and beautiful throughout the season. A large panel or piece of a wall so furnished gives new life and beauty and peculiar brilliancy to the spring-tide. Placed side by side or between the plants of the early yellow *Jasminum nudiflorum*, the effect is still more rich and beautiful. Both may become yet more artistic if the two plants are allowed to overlap or intermix somewhat the two colours, each contributing to enhance each other's beauty. It is a somewhat singular coincidence that just as the beautiful flowering Currant is grown on the wall, so this hardiest and most showy of all the Jasmynes is seldom or never found on it. But throughout the whole of Ireland and the milder parts of England this golden Jasmine is hardy in the sheltered shrubbery or home woods, and as on walls, so in the foreground of shrubberies, the two plants go admirably together.

Every planter of experience is familiar with the charming habits of most of the *Ribes*. All they need is room and to be let alone to grow into fine bushes of matchless symmetry and exceptional grace. It is very different with the Jasmine. It is a trailing plant, though not exactly a climber, for if left to itself it will form a huge mass of almost any desired area. But so treated, it is readily knocked about by high winds or borne down almost flat with the ground by heavy falls of snow.

To avoid this, the simplest way is to furnish each plant with a stout stake from 2 feet to 1 yard high when planted. This imparts stability to its centre, and beyond this almost any sort of pruning or training, or no sort of either may be adopted. In general, the less of either, the more effective and strikingly beautiful the Jasmine becomes as a shrub. Another simple and striking way of treating these plants is to plant them together and allow the Jasmine to grow up with and among the *Ribes*. In this case it will be needful to interfere somewhat vigorously to prevent the Jasmine overrunning too much and too far the *Ribes*. It is easy for the eye of taste and the hand of skill so to adjust the balance

of crimson and golden as to make the contrasted combination as perfect as may be.

There is yet another admirable method of combining these two plants. In shrubberies liberally furnished with this fine Ribes or the more common species *R. sanguineum*, plant a good many golden Jasmines against the stems of deciduous trees or among masses of scrambling or climbing Briers or Roses, train the Jasmine lightly to these, and allow it to scramble down to meet or partially overrun the Ribes. The effect will be as rich and pleasing as any that the entire season affords, and it is one that may be enjoyed by almost every possessor of a garden, as hardly any two plants can be more plentiful and cheap than these two delightful hard-bingers and substantial enrichers of our shrubberies and woods in the springtime. D. T. F.

THE FRAGRANCE OF THE DOUGLAS SPRUCE.

WHILE "W. G." gives almost an exhaustive list of the merits of this useful and handsome tree, he omits to name its sweet and pleasant fragrance. Its branches, merely handled or slightly squeezed in the hands, emit an odour at once pleasing and sanitary; few branchlets are more welcome in sick or sleeping rooms to those who are in the secret of its refreshing fragrance. As they fade, and before the needles fall they may be burned in the grate or on a hot shovel, and medical men who have had experience of this Spruce as a febrifuge are sure to ask for it again. A few plants are worth growing in small gardens for their fragrance only. Permit me to endorse "W. G.'s" views about the great superiority of the glaucous variety of the Douglas Spruce. The paler the strain, the worse and the weaker; the more verdant and semi-glaucous, the more rapid the growth and robust the health of this fine Spruce. It is the existence of these two or more varieties that has originated and sustained the great variety of opinion about this fine tree. In some localities one meets with few of the viridis type; and in such, be the soil or shelter what it may, the Douglas Spruce is more or less sickly and stunted. The trees are mostly thin of foliage and branchlets, and have a sickly hue.

While experience with this fine Spruce in widely differing localities leads me to endorse all that "W. G." so well says upon the need of considerable shelter and good soil to its rapid growth, I would nevertheless emphasise even more than he does the necessity of starting with the verdant variety if success is to be reached in the growth of this Spruce for timber. Side by side with the common Spruce it beats it a long way in speed, while the timber is altogether cleaner, easier worked, and hence more valuable. It is also said to be equally durable, though here possibly the ratio of growth may come in as a disturbing force. Probably the fastest grown Douglas Spruce from the bottom of a fat valley may not yield such durable timber as that grown more slowly on poorer soils and in more exposed localities. HORRUS.

Magnolia Campbelli. In THE GARDEN March 19 (p. 280) "T. B." speaks of this Magnolia as a beautiful white-flowered kind, suitable for the back wall of a conservatory, and further states it is a native of China. *Magnolia Campbelli* is a native of the Himalayas, and is in this country so shy flowering, that it cannot be the plant intended. All tree-lovers were for many years anticipating with interest the blooming of *M. Campbelli*, for it was described by Sir Joseph Hooker in its native country as flowering abundantly in April, at the end of all the branches, when the tree is as yet perfectly leafless, the blooms varying in colour from white to deep rose, or almost crimson, and in size from 6 inches to 10 inches, the scent being faint. The first and, so far as I know, the only place it has flowered in Great Britain is in the gardens of Mr. W. Crawford, Lakelands, near Cork, where it bloomed in 1881, when a drawing of it was made for the *Botanical Magazine*. If "T. B.'s" plant is really *M. Campbelli*, many of your readers will, I am sure, be pleased to hear of its flowering, but I strongly

suspect there has been a mistake, and perhaps "T. B." will enlighten us on that point. The description of a deciduous kind with white flowers, and a native of China, will apply to the Yulan (*M. conspicua*), but it is quite a hardy tree, though the blooms from their earliness are occasionally injured by late spring frosts. H. P.

ROSE GARDEN.

T. W. GIRDLESTONE.

ROSE-GROWING IN AMERICA.

IT is most satisfactory to feel that a mere touch of Rose lore or love makes all men and nations kin. Difference of race, country, nationality, vanish as we meet among and feel we are all but one family among the Roses. One of the chief charms of Mr. Falconer's notes is the home-like character of his cultural instructions, and the home ring of the names of his Roses singled out for special praise. With the two exceptions of *Bon Silene* and *American Beauty*, most of his favourites are also ours. America being a big country, full of big things, it is only natural to expect that size in Roses should score more points there than in our tight little island. But there is small exception to be taken to Mr. De Forest's selection on this head, unless, perhaps, in regard to Paul Neyron. But there is more to be said in favour of this giant than has yet been said on this side the big pond. Even with us there is a great difference between Paul Neyron at midsummer and in the autumn. At the latter season it loses much of its size and nearly all its coarseness, and is in many gardens in great request for autumnal cuttings. Under glass Paul Neyron becomes yet more refined alike in form and colour. Forced yet earlier, as it seems to be by Mr. De Forest, it is easy to understand its becoming popular for other qualities besides its mere size. It is refreshing also to find such an old favourite as *General Jacqueminot* still held worthy to rank among the most valuable Roses for forcing in America. This fine old Rose has greatly degenerated of late years at home, or possibly it would be more true to say that its cultivation has been given up for that of newer Roses of less merit either in constitution, continuous bloom, or brilliancy of colour. As to *General Jacqueminot*, it may have equals, but can never be eclipsed. And that how home-like are most of the other names—*La France*, *Niphetos*, the two *Mermets*, *Captain Christy*, *Madame Gabriel Luizet*, and *Magenta Charta*, the latter of which Mr. Falconer seems to run abreast with Paul Neyron as approximating to it in size and contrasting well with it in colour. *Catherine Mermet* and its white sport *The Bride* seem the most extensively grown. It is remarked incidentally that *Niphetos* is not grown on its own roots, without any information being given as to the stock used. My experience with this fine Rose is that few or no Roses need a stock less, as it grows freely indoors and vigorously in warm sheltered nooks and corners out of doors on its own roots.

It must be confessed that it is a serious disappointment to us Britishers that *Her Majesty*, even under the fostering conditions provided for it by Mr. De Forest, has not yet become, but is still waiting for more porous soil to make it supremely beautiful. We trust the new and lighter treatment will restore *Her Majesty* to her pristine splendour in this her jubilee year. Mr. De Forest's compost, liquid and solid dressing, and general treatment seem all eminently calculated to bring forth those brilliant results Mr. Falconer has so vividly described, and in which rosariums on both sides of the Atlantic rejoice in common. As to reaping the almost harvest of flowers from maidens rather than cut-backs, it is doubtful whether this experience coincides with that of the majority of Rose growers in this country. By the way, one is tempted to inquire, what becomes of the maidens? Surely they cannot be sacrificed; as after one year's rich fostering under such strengthening conditions they must be splendid stuff for a second venture or out-of-door furnishing. Mr. Falconer's list can hardly be termed exhaustive, as otherwise the omission of our

favourite golden or fawn-coloured Roses, such as *Maréchal Niel*, *Céline Forestier*, *Triomphe de Rennes*, *Lamarque*, *Gloire de Dijon*, *Ophirie*, *Mdme. Welch*, &c., seems strange. It can hardly be that *Maréchal Niel* is not grown on account of its large size by a nation in which Paul Neyron is popular; neither can it well be that such lovely pink Teas as *President* and *Souvenir d'un Ami*, or such exquisite creamy whites as *Souvenir d'Elise Varden*, *Marie Van Houtte*, *Mdme. Bravy*, *Innocente Birola*, to say nothing of *Devoniensis*, are not grown by Mr. De Forest. Many other fine and brilliant Roses do not seem to be grown largely or at all by this successful cultivator under glass. It would be interesting to know if difference of climate greatly affects the character, beauty, or usefulness of the following Roses in America: *Alfred Colomb*, *Beauty of Waltham*, *Baroness Rothschild*, *Boule de Neige*, *Charles Lefebvre*, *Dr. Andry*, *Duke of Edinburgh*, *Edouard Morren*, *John Hopper*, *Jules Margottin*, *Mdme. Victor Verdier*, *Marchal Vaillant*, *Marie Baumann*, *Marie Rady*, *Prince Camille de Rohan*, *Senateur Vaisse*, and *Victor Verdier*. It will be seen that these are rather representatives of classes of Roses than an exhaustive list of the best varieties; and any particulars of their doings in the open or under glass in America will be welcomed by all your Rose readers. D. T. F.

A never-failing Rose.—This term may be justly applied to *Gloire de Dijon*. We grow it against walls and as standards in the open air, and in various positions under glass, and it never fails to bloom freely everywhere at the right time. One plant under glass is very old, and I have cut thousands of blooms of it in past years, and now it flowers as freely as ever. It is the alpha and omega of Roses. Its qualities cannot be overpraised, as it grows so freely and blooms so profusely without any particular care. I cannot imagine any garden being without it, and I can advise its universal culture without fear of a mistake being made in growing it. —CAMBRIAN.

Pruning Roses.—It is stated in THE GARDEN (p. 275) that "the objection generally urged against late pruning is that the plants bleed so much more than when pruned before any material growth has been made at the ends of the shoots." May I ask what authority on Rose culture has urged this plea? I am curious because, so far as my experience goes, the Rose does not bleed to any appreciable extent. One understands what bleeding means in the case of the Vine or in a tree like the Sycamore, from which the sap literally runs, but who ever saw a Rose bleeding freely; and if it does not bleed, why discuss the subject in relation to pruning? Why some plants bleed so much more than others is a mystery, and it is well to bear in mind the fact that some plants do bleed to their injury, but they are the exception instead of the rule, fortunately.—J. S.

Mulching Roses.—If the present low rate of rainfall continues, all Roses will be greatly benefited by having a mulch laid on the surface over the roots. Especially is this necessary in the case of newly-planted Roses whose roots have not had time to get a good hold of the soil, and nothing is equal to half-rotten cow manure. To be of any benefit to the plants, it requires to be laid to a depth of 3 inches, and when the plants are in beds the whole of the surface should be covered with the manure. Single plants growing in the form of standards or bushes should have the ground covered 18 inches from the stem all round; where the ground round the plants has been much trodden, the surface should be stirred up a little before the mulching is put on. In dry, sandy soils the short Grass may be used for mulching if there is no manure available. As this quickly dries up fresh applications will be necessary at intervals of two or three weeks.—J. C. C.

Ensuring flowers on Marechal Niel Rose.—There are many *Maréchal Niel* Roses grown, but all do not flower freely. The reverse is almost the rule, and in many cases a plant which produced a fine lot of blooms last year will only bear a few this season. As an instance of the kind, I may say

that at Easter, 1886, we had a *Maréchal Niel* which produced scores of grand blooms, but the results at Easter, 1887, were almost nil, and yet the plant is as bulky and quite as healthy, but the wood is quite different in character. The plant in 1886 was mainly composed of long, thick shoots, which were produced and matured the previous year. These burst into growth at every eye, and each of the shoots produced a flower. This was satisfactory, but in the summer of 1886 a few very long strong growths were formed, the wood only developing into a great number of small branches, and it is these which are now failing to flower freely or produce large blooms. In the future we will take care that these small growths be cut off early in the season, and only long shoots will be encouraged to grow and mature, when they will develop fine blooms, as was the case in 1886, and by securing these robust growths annually, free blooming will be the invariable result. — CAMBRIAN.

HEATING BY STEAM IN AMERICA.

If what Mr. William Falconer says in his deeply interesting article from the *American Florist* in THE GARDEN (p. 207) concerning the economy of steam heating can be confirmed, then we in this country have been advancing backwards for many years, and must once more return to the use of steam. Were the difference one of a trifling percentage the matter might be of little moment, but when it becomes a matter of saving almost half the coal consumed, the question of economy between steam and hot water must needs be fought over again. Nothing can be more positive than Mr. Falconer's statement. Eight tons of coal in the steam-heaters give the same results as fourteen in the hot-water apparatus. Assuming that the quality and price of the coals used for both are alike, we have had no statement advanced of such superlative horticultural importance for years. For coal being the most costly factor in producing horticultural produce out of season, it follows that if the quantity can be thus reduced, producers and consumers alike must share in the benefits, and the science and practice of horticulture receive a new and powerful stimulus.

Before forming a correct judgment on the matter, further information must be had as to the exact nature and character of the steam-heaters and the hot-water apparatus pitted against each other by Mr. De Forest. Possibly Mr. Falconer or the *American Florist* will kindly furnish full details and plans of both. Are each the best and most economical of their kind? It is the more needful to be assured on this point, for even among hot-water apparatus it is no uncommon thing to find some that will do equal or even more work with half the fuel as others.

The sources of waste are too numerous to mention, and only one will be named at present — boiler setting. The waste of coal cast into this great gulf every year is probably equal to that which sustains our semi-tropical climates under glass in spite of wind and weather. Ignorant stoking also wastes its thousands of tons of coal a day. But I will not dwell on those points. My great object is to obtain further information as to this fuel-saving steam-heater used in Mr. De Forest's huge Rose nursery across the Atlantic.

It may very well be that what Mr. Falconer says is perfectly true. A good many horticulturists in this country are of opinion that steam-heating never had a fair trial here. Steam as a source of heat, as well as a motive power, was almost in its infancy when it was ushered into our hothouses. Little or nothing was known then of the economical production or use of steam. The science of the evolution and economical application of so much calorific or motive power from each pound of fuel had hardly been discovered. No one conversant with the use of coal in horticulture can affirm that the science of scientific economy in its use has yet been perfected. Every day almost more driving, lighting, or heating force is got out of our coal for manufacturing or commercial purposes. But it must be admitted that our coal-saving expedients in horticultural heating

are still far behind those employed for trade and commercial purposes.

This brings me to the following probable explanation of Mr. Falconer's facts. Possibly the steam-heater is the last and best thing out of its class furnished with all the fuel-saving, heat-concentrating, and economising appliances discovered by the latest science, and used by the most advanced practice. Further, it is just possible that this latest and best steam-heater is pitted against an antiquated and wasteful hot-water apparatus. If the two are thus inequally matched, there is nothing wonderful in the facts recorded. But if both are the best of their kind, and the consumption of fuel is as eight to fourteen in favour of steam, then, indeed, are we on the eve of a great revolution, or rather retrogression, in our modes of heating. No one need fear any injuries through the adoption of Mr. De Forest's steam-heaters, as steam-heat, though of a higher temperature, is, as everybody knows, as pure as that from hot water. We want, first of all, plans and descriptions of these steam-heaters, and as soon as practicable a few of them in operation at our great shows in London, Manchester, Edinburgh, and other large towns. If reasonably cheap, and as economical as stated, their introduction here will mark a new era of greater wealth and enlarged prosperity to British horticulture.

FERNS.

W. H. GOWER.

CLUB MOSSES.

(LYCOPODIUMS.)

THIS division of the Lycopods contains many plants of great beauty totally distinct in character from the Selaginellas. They have been much neglected by plant growers, and consequently have gradually become scarce. On a recent visit to Kew, however, we observed numerous examples thriving in the Fern house there. These plants are well deserving the notice of those forming a collection of Ferns and their allies. Amongst the beautiful tropical kinds now growing at Kew may be noted *L. verticillatum* (a native of the Mascarene Islands), which is a stout-growing plant, with branching, pendent stems, densely clothed with linear lanceolate dark green leaves, arranged in whorls. *L. phlegmaria* is a handsome species of quite a different type of beauty; its stems are much branched, from 1 foot to 2 feet long, bearing numerous shining, bright green, cordate leaves, the ends of the stems ornamented with long, many-branched, pendulous tassels of catkin-like sporangia. It appears to be abundant in the Fiji and Philippine Islands, and also found in the northern parts of Queensland and various other places. *L. phyllanthum*, from Tropical Asia, is a similar plant, but somewhat more robust in all its parts. *L. taxifolium*, from Jamaica and various others of the adjacent islands, is a stout, pendulous plant, growing a foot or more in length, the stems being abundantly furnished with bright green acuminate leaves; the sporangia are not produced in tassels at the ends of the shoots, but are situated at the bases of the upper leaves. *L. squarrosum* grows to 3 feet or 4 feet in length, its stout, forked stems being clothed with large, linear-lanceolate, deep green leaves, the points of the shoots ornamented with pendent spikes of sporangia. It is a native of the Polynesian Islands. *L. dichotomum*, from Brazil, and *L. gnidioides*, from the Cape, are thriving well in this collection. Various other species were recently to be found in the principal London nurseries, notably *L. ruscifolium*, introduced from Borneo, by Mr. Low, of Clapton; it has slender, red stems, which are much ramified, sparingly clothed with shining, dark green leaves, somewhat cordate

at the base, tapering to a sharp point. *L. laterale* is another interesting plant, introduced from New Zealand by the Messrs. Veitch, of Chelsea. It is erect in growth, with slender, much-branched, terete stems, densely clothed with slightly spreading linear, sharp-pointed leaves of a bright green. Several species have also been introduced by the Messrs. Jackson, of Kingston, the most noteworthy being *L. Hookeri*, from the East Indian Islands, a bold and handsome form, resembling a gigantic *L. phlegmaria*, the stems are stout, branched, some 2 feet or 3 feet in length, with large, flat, lanceolate-acuminate leaves of a bright shining green; whilst its pendulous tassels of sporangia are from 4 inches to 6 inches long. *L. linifolium* is a native of the West Indian Islands, and is also found in Venezuela on trees at an altitude of 5000 feet to 6000 feet. It has long, slender, much-divided stems, with linear-lanceolate, shining, bright green leaves. The pretty little, erect-growing *L. uliginosum*, from Australia, thrives admirably in Wardian cases. Lycopodiums were great favourites with the Messrs. Rollisson, of Tooting, also, who introduced numerous species, of which we may mention *L. serratum*, from the neighbourhood of Yokohama, in Japan. Its stems are about a foot high, once or twice forked, profusely clothed with flat, ovate-lanceolate bright green leaves, which are stalked and serrate on the edges. *L. aloifolium*, from the Neilgherry Hills, is a remarkable plant, 12 inches or 18 inches long. The stems are stout, branched, and densely clothed with broad, obtuse, dark green leaves nearly half-an-inch long. *L. reflexum*, introduced from Merida, where it was found upon trees at an altitude of 6000 feet to 7000 feet, is a very handsome species, some 12 inches or 18 inches long, the stout stems thickly clothed with long, linear, reflexed, dark green leaves. This plant enjoys heavy shade. *L. dendroideum*, a species from North America, which is perfectly hardy in this country, and which gives a pleasing variety to the open-air fernery, may be likened to a miniature Fir tree. *L. densum*, from New Zealand, grows about a foot high, its numerous and many-branched stems being clothed with closely-set, short imbricating leaves, the plant resembling a miniature Juniper. Mr. Williams, of Holloway, must be credited with the introduction of some few species, the most notable of which are *L. cernuum*, *scariosum*, and *L. volubile*. The first is a plant widely distributed in the Tropics, but although a plant with so wide a range it does not differ much in anything except in the height. The stems are woody and much branched, furnished with small, linear, needle-like, pale green leaves, the tips of all the branches ornamented with a small, pendulous, hairy, cone-like catkin containing the sporangia. This plant is said to grow upon limestone rocks. *L. scariosum* is a beautiful plant that should be well known in Fern collections by this time; it is found on the mountains of Jamaica, and is common in the woods which clothe the mountains in the northern island of New Zealand, and also occurs in similar situations in the Andes of South America. It grows from 1 foot to 2 feet high, branches spreading and leafy, leaves alternate-lanceolate, winged to the stem, and soft pale green; the spikes bearing the sporangia are erect, cylindrical, some 3 inches long, the ends of the bracts turned back (revolute). *L. volubile* is also a native of New Zealand and various islands in the Pacific Ocean; its leaves are somewhat similar to the last-named species, but the sporangia are borne in short catkin-like tassels on separate branches, and the plant, moreover, is scandent, ultimately becoming a lofty climber.

The cultivation of Club Mosses has not hitherto been attended with a great amount of success, and hence, notwithstanding their extreme beauty, they have been somewhat neglected, and many kinds once grown in this country have been lost. These plants appear to suffer greatly by removal from their native haunts, the check they receive through having their roots torn and lacerated proving fatal in most instances. This source of failure, however, could be to a great extent remedied by sending them home upon portions of the material on which they are found, thus avoiding any disturbance to the roots. In the case of epiphytal kinds, these should always be suspended in baskets, the drainage free and open, and the soil used should be in the shape of knobs of spongy peat, and mixed with a little Sphagnum Moss. The terrestrial kinds should be placed in well drained pots or pans, and potted in the same compost, to which may be added with advantage some sharp sand and a few nodules of charcoal, for although they enjoy an abundant supply of water, they ought never to become saturated. In the treatment of these plants the cultivator often errs in placing them in too high a temperature; some few species, however, require the heat of an East Indian house, but nearly all the epiphytal kinds grow at as great an elevation, and oftentimes associated with *Odontoglossums*. This in some measure should be a guide as to their requirements.

ORCHIDS.

W. H. GOWER.

ORCHIDS IN THE HOUSE.

THAT Orchids may be grown and flowered in a satisfactory manner by those who do not possess glass houses was strikingly exemplified

did not receive much sunshine were two large Wardian cases, one being filled with a pretty collection of Filmy Ferns, the Killarney Fern (*Trichomanes radicans*) being specially notable, and the other contained numerous Orchids, many of which were flowering; these also had been established a little over two years. They had been purchased as established plants (not newly imported pieces), and the cheap kinds had been selected to try the experiment. The interior of the case had been fitted up with virgin

Sphronitis grandiflora growing on cork.

cork to represent a rough, rocky boulder with many cavities, these cavities or pockets being filled in with a mixture of fibrous peat, Sphagnum Moss, and nodules of charcoal of different sizes, and in which the plants were placed. The whole had been surfaced with live Sphagnum Moss, and judiciously planted with several kinds of the creeping Selaginellas, the effect produced being truly charming. This style of Orchid growing should not be overlooked by dwellers in towns, for nothing appears to be

one or two seasons' growth in this country, as newly-imported plants are by no means ornamental, and oftentimes require considerable care to establish. The species flowering in the case in question at the time of our visit were *Odontoglossum Rossi majus*, *O. Lindleyanum*, *Oncidium cucullatum*, *Masdevallia ignea*, *Sophronitis grandiflora* (which is well illustrated in the accompanying cuts), and *S. cernua*; whilst *Odontoglossum Alexandrae* (*crispum*) and *roseum* were just pushing up a spike each; so also were *Cypripedium insigne* and *Ada aurantiaca*. *Epidendrum vitellinum* and *Cypripedium venustum* appeared quite happy in their situation, but were not flowering. Several examples of these twelve kinds were dotted about, and all appeared to be in a thriving condition. This system has been adopted by one who formerly possessed glass-houses, and a nice collection of Orchids which were grown by himself, so that a certain amount of knowledge as to the best kinds to select and of their requirements was brought to bear upon the experiments at starting. The plants growing in shallow baskets in the south window were *Lycaste Skinneri*, *Oncidium tigrinum*, *Laelia anceps*, *L. albida* (the three latter flowering), *Lycaste aromatica*, and *Cattleya Harrisoniana*. These plants were suspended outside the window in the open air in the summer, sometimes when a soft warm shower was falling and sometimes during the bright sunshine, but they had never remained in the open through the night. The plants all appeared to be in fairly good condition, and we shall be curious to watch their progress. One great want to render the growth of such plants in the house agreeable is a hanging basket that will prevent drip.

Orchids at Welham Hall.—There may now be seen at Welham Hall, the residence of Mr. W. Birks, a very fine collection of Orchids. *Dendrobium Wardianum* and the albino variety are flowering very freely, as also *D. crassinode*. The *Phalaenopsis* are also well done. Some fine forms of *Cattleya Trianae* are grown, and the choicest varieties of *Odontoglossum Alexandrae* and *vexillarium*. The plants are all in rude health.—F. C.

Cœlogyne cristata.—I am glad to see further remarks on this subject, as it is only by comparing notes that we can get at the real truth. When I first wrote about it it was to take exception to some remarks which stated that it would succeed well in a cool greenhouse. There is considerable difference between this and a cool Orchid house. Where *Masdevallias* are usually grown in winter the temperature is not materially different from that of the cooler *Cattleya* temperature—50° as a minimum. Mr. Vicary states that his plants were grown with *Masdevallias*, but does not give temperatures. His remarks are of no practical value because of this. The East India house is too warm. When he states that the plants were shifted from the *Masdevallia* house into warmer quarters, viz., the back stage of one of the lean-to houses, no one can tell what the temperature was; it might be too warm, which would be a greater evil than too cool. Again, the back stage of a lean-to house, probably a long distance from the glass, where they would not get sufficient ventilation, is the worst possible position for them. The remarks by "C. R." come under the same category; he saw "a batch . . . grown under what might be termed cool treatment, as heat was only applied in cold or dull weather." He says nothing about the nature of the other occupants of the house, nor does he give the winter minimum temperatures. Applying heat in cold weather necessitates

Sphronitis grandiflora (natural size).

recently when visiting a gentleman's residence in the suburbs of London, where *Laelia anceps* and *L. albida* were flowering in a sunny window of a sitting-room. These plants were not recently purchased from a nursery, but had occupied the same position for two years, saving an occasional removal to the open air on genial days in the summer months. In the recess of a window on the opposite side of the room which

more easy of accomplishment than to obtain and maintain a good display of these showy and popular flowers if the kinds are carefully selected. The taste for these plants may, moreover, be indulged in by those of limited means, as the majority of the varieties suitable for this purpose may be purchased for a few shillings each. It is necessary, however, to commence with established plants, that is to say, plants that have made

its application all through the winter. No heat is necessary during summer, even for Cattleyas. My contention is this: *C. cristata* will not thrive in a cool greenhouse at all. It will grow and flower in an ordinary cool Orchid house, and all the better if the house is span-roofed and well exposed to the sun. The East India house is too hot. The best place is the Cattleya house, with a winter temperature of 50° to 55°; summer temperature, 55° to 60°—minimum, of course. If the cool-house temperature comes near these figures, I have no doubt the *Celogynes* will succeed remarkably well.—J. DOUGLAS.

Dendrobium fimbriatum. This is one of the easiest cultivated plants in the whole Orchid family. We have half-a-dozen plants of various sizes crowded with spikes. None of them ever fail to flower freely. The treatment is this: when the plants have passed out of bloom we place them in a high temperature, say, 65° at night, shutting up the house with sun-heat until the temperature reaches 90° to 100°. The plants may be repotted at this time, if it is necessary to do so. Fill the pots half full of drainage. The potting soil should be turfy peat and Sphagnum in equal proportions, with some potsherds and charcoal to keep it open; we press the potting soil in moderately firm. The plants will make roots freely and grow with great vigour all through the summer and early autumn months. When growth is completed, gradually reduce the water and give none at all in winter, unless the stems are showing signs of shrivelling, when enough must be applied to prevent this. I do not keep them very cool in winter; they are placed in a light position in the Cattleya house. I ought to have stated that when making their growth they are not shaded much, only sufficient to prevent scorching. They produce their flowers in the Cattleya house.—J. D.

Angræcum citratum.—This is a small free-growing plant, introduced from Madagascar about twenty years ago. For a long time it was very scarce in this country. In growth it resembles somewhat the habit of a small *Phalenopsis*, such as *P. rosea*. It should be grown upon a block of wood, or in a small basket, and be kept well exposed to the light, but shaded from the influence of the burning sun. The spike is pendulous, 9 to 12 inches long, and bears fifteen to thirty flowers; these are flat, slightly less than an inch across, arranged in a two-ranked manner, and closely set together. The colour is pale citron-yellow, and in some varieties almost white; the lip is furnished with a long flexuous spur. This *Angræcum* is a prolific bloomer, and many dozens of plants are now flowering in Mr. Low's nursery at Clapton; most of these bear three or more spikes each, and the whole have a charming effect.—G.

Steaming Orchids.—This system is now quite the recognised method of destroying insect pests in Mr. Williams' nursery, the advantages claimed for it over fumigation being, 1st, that the house is rapidly filled; 2nd, that the operator is not required to be inside the house; 3rd, that Orchids that could not be fumigated (without causing them to become spotted and lose their leaves are not in the least affected by steaming; and lastly, although not least, the operation may be performed in a house full of flowers, and Ferns with delicate fronds, without the slightest damage accruing therefrom. On a recent visit we saw such flowers as *Celogyne Lemoniana*, *Odontoglossum Ruckerianum*, *Cymbidium eburneum*, besides a host of Cattleyas, Calanthes, and various *Cypripediums*, which had been subjected to the steaming, but the flowers did not exhibit the slightest speck or blemish; neither had the young and immature fronds of the Ferns which had passed through the ordeal suffered in the least.—G.

SHORT NOTES.—ORCHIDS.

Odontoglossum triumphans—Referring to the remarks by "G." in THE GARDEN (p. 325), I agree with him that this is a very beautiful species. Indeed I think it the finest and brightest of all the yellow ground *Odontoglossums*. The only reason it is neglected I should imagine is that growers cannot afford to purchase quantities of it. It is usually found growing with *O. Pescatorei*, and those purchasing unflowered plants of the last named may find

O. triumphans among them, just as we get *O. bystris*, *O. luteo-purpureum*, *O. Wilckeanum*, &c., amongst importations of *O. crispum*.—J. P.

SOCIETIES AND EXHIBITIONS.

ROYAL HORTICULTURAL.

APRIL 12.

THE meeting of the fruit and floral committees held in the conservatory was rendered remarkably gay and effective by the large groups of *Narcissi* staged by Messrs. Ware, Barr and Son, and Collins and Gabriel. It was also rendered particularly attractive by the new feature of cut *Roses* from America, which were staged in excellent condition; and by numerous interesting and showy groups from various exhibitors.

The following first class certificates were awarded, viz., to *Rose Paritan*. Plants in flower and cut blooms of this *Rose* were staged; they had been sent from America to this country for exhibition, eleven days being occupied in transit; they arrived in excellent condition. The foliage of this variety is stout and of a deep metallic green; the flowers large, creamy white, of exquisite form; petals round, and of good substance; whilst its staying properties may be judged of by the journey to which they had been subjected. One dozen of the cut blooms had been enclosed in an hermetically-sealed box, and an equal number had travelled in tubes of water in an ordinary close box; there did not, however, appear to be any appreciable difference in their condition. Judging by the examples staged, it is a great acquisition. It was exhibited by Messrs. W. Paul and Sons, of Waltham Cross, by whom we believe it will be distributed in this country. *Rosa polyantha minutifolia alba* and *Rose Golden Fairy*, exhibited by Mr. H. Bennett, Shepperton; the first, a dwarf plant with small leaves and pure white double Daisy-like flowers; the latter being freer in growth, with ample leaves and flowers of a delicate creamy golden colour. Violet *Victoria*—a large group of this as shown by the raiser, Mr. Chambers, of Isleworth, proved to be a most profuse bloomer; the flowers are very large, double, of a dark purple colour. It is said to be a cross between *The Czar* and *Neapolitan*, having the colour of the former and the fragrance of the latter parent. *Cattleya Trianae Schroederæ*, shown by Baron Schroeder, Baron F. de Rothschild, Tring Park, and Mr. F. Wigan, Clare Lawn, East Sheen, is a form with large and stout flowers, the sepals and petals being white, flushed with pink or flesh colour; lip slightly deeper in colour, with orange in the centre, which colour is continued round the convolute middle lobe. *Odontoglossum Pescatorei virginale*, with a long raceme bearing large pure white flowers, stained at the base of the lip with yellow, the form of the flowers giving one an idea of its being a probable hybrid between *O. Pescatorei* and *O. citrosum*. Exhibited by Baron Schroeder. *Adiantum cuneatum Gordonii*, a crested variety indistinguishable from *grandiceps*; and *Cineraria Alexander Warwick*, of dwarf habit; flowers crimson, the lower petals being quilled, the turned-over portion soft rose. Both were exhibited by Messrs. Gordon and Son, nurserymen, Edinburgh. *Narcissus cyclamineus*, shown by Messrs. Barr and Son, King Street, Covent Garden; *Cineraria Wm. Pratt*, a large double blue form, shown by Mr. Pratt, Longleat Gardens, Warminster; *Cyclamen Queen of Crimsoms*, a very deep crimson-flowered variety, exhibited by Mr. J. Odell, Hillingdon; *Cypripedium leucorhodon*, a cross between *C. Sedeni* and *C. Schlimi albiflorum*, a bold growing plant with pale rose-coloured flowers and a large pouch; *Amaryllis Nonpareil*, a flower of exquisite shape, good substance, and rich, deep crimson in colour; *Amaryllis Edith Wynne*, a form of the reticulata section, petals crimson, broadly margined with white, exhibited by Messrs. James Veitch and Sons; *Auricula Sir Wm. Hewitt*, a deep purple, maroon-flowered variety, and *Abbé Lizst*, green-edged, both shown by Mr. J. Douglas, Great Gearies, Hford; *Odontoglossum crispum* (Mr. Thompson's variety), bearing a spike of very bold and handsome flowers, each measuring some 4½ inches across; white, distinctly blotched with bright cinnamon-brown, the raceme bearing nine flowers arranged in a very dis-

tinged two-ranked manner; shown by Mr. W. Thompson, Stone, Staffs.

Messrs. Barr and Sons, King Street, Covent Garden, staged a very fine group of *Narcissi*, containing most of the leading forms, for which a silver Banksian medal was awarded.

Mr. Ware, of Tottenham, received a similar award for a large group of *Narcissi*, fringed with *Chionodoxa Luciliae*, *Anemone fulgens*, *Allium neapolitanum*, *Freesia refracta*, and other spring flowers, also an interesting mixed group, amongst which were fine examples of *Primula rosea*, *cashmeriana*, and *nivea*, *Anemone Pulsatilla*, *Zephyranthes carniola*, *Ophrys tenthredinifera*, *Lachenalia*, &c.

Messrs. Collins Bros. and Gabriel, Waterloo Road, London, were also awarded a silver Banksian medal for a magnificent group of *Narcissi*, edged with *Anemone splendens*, both single and double forms; *A. fulgens multipetala*, and various other spring flowers. A silver Banksian medal was awarded.

Mr. B. S. Williams, of Holloway, staged a pretty group, amongst which we noted a very distinct and novel form of *Anthurium Scherzerianum* named *atrosargineum*, in which the spathe was of a very deep blood colour, the blue-flowered *Tillandsia Lindenii*, various *Sarracenias* bearing handsome flowers, the rare *Vanda cristata*, *Ochna multiflora*, a finely-flowered specimen of *Rhododendron Veitchianum*, and numerous profusely-flowered plants of the best form of *Boronia megastigma*, &c.

The Royal Gardens at Kew contributed a very interesting group of plants which have somewhat gone out of fashion of late years, but assuredly would again become popular if more frequently seen at such gatherings as these. The most notable were several kinds of *Boronias*, *Epacris*, *Acacias*, and *Chorozemas*; the beautiful and rare *Pentapterygium rugosum*, various *Grevilleas*, *Darwinias*, &c. From the herbaceous department also came the exquisite *Primula Reedi*, with hairy leaves and white flowers, almost like a *Snowdrop*; *P. marginata densiflora*, and *P. spectabilis Clusiana*. A silver Banksian medal was deservedly awarded.

Messrs. J. Laing and Son, Forest Hill, staged a large plant of *Dendrobium Ainsworthii*, bearing some 200 of its beautiful and deliciously fragrant flowers, for which a cultural commendation was awarded. Messrs. Laing also staged several specimens of *Cattleya Lawrenceana*.

Messrs. Veitch and Sons, of Chelsea, staged a handsome group, consisting of *Amaryllis*, *Azalea*, &c.; notable were *Amaryllis Illustrious*, crimson flushed with carmine; *Nonpareil*, rich crimson; *Pannure*, bearing six flowers on the truss. *Azalea calyciflora*, a variety in the way of *obtusa*, but with the calyx enlarged and coloured, and a pretty white form of *Azalea obtusa* named *alba*, were noteworthy. *Andromeda japonica*, bearing a profusion of pendent racemes of white, bell-shaped flowers, was also conspicuous.

Mr. F. Wigan, Clare Lawn, East Sheen, contributed a well-bloomed specimen of *Dendrobium Findleyanum*.

Baron Schroeder, of The Dell, Egham, sent *Odontoglossum Pescatorei*, a cut spike of the unique and beautiful *Odontoglossum Pescatorei Veitchianum*.

Mr. G. F. Wilson, Heatherbank, Weybridge, sent a basket of cut flowers, containing hybrid *Hellebores* and seedling *Primula denticulata*, &c.

Mr. J. Douglas staged a few excellent new seedling *Auriculas*, the most notable being *Snowdon's Knight*, *Lady of the Lake*, *Innocence*, and two others previously referred to.

Mr. Measures, of Cambridge Lodge, Camberwell, sent cut blooms of a very fine, pure white-flowered *Pelargonium* named *Miss F. Measures*, which was stated to retain its purity, which the majority of the white varieties do not.

Mr. R. Dean, of Ealing, exhibited the pretty little *Primula longibarda*.

Sir G. Macleay, of Pendell Court, sent a collection of cut blooms, amongst which we noted large panicles of *Fuchsia arborea*, *Hardenbergias*, numerous varieties of *Vandas* and other *Orchids*; *Paulownia impe-*

rials, and the Natal *Streptocarpus Polyanthus*, &c. A bronze Banksian medal was awarded.

Messrs. Lane and Son, Berkhamstead, contributed a remarkably fine group of the Japanese *Azalea mollis*, with very large flowers, the colours being extremely variable. A silver Banksian medal was awarded.

Mr. H. B. May, of Edmonton, staged a striking and well-grown group of small Ferns, containing many species and varieties. A bronze Banksian medal was awarded.

Mr. F. A. Philbrick, Q.C., Bickley, sent *Cymbidium eburnum* Philbrickianum, with pure white flowers, and the old, but seldom seen, *Cattleya amethystina*.

Scientific committee.—Mr. Maw exhibited the following species of *Crocus*: *C. biflorus* var. *Pestalozzei*, from near Constantinople, with a very small white perianth; *C. minimus*, DC., from Ajaccio, Corsica, with dark purple outer petals and lighter coloured ones within; *C. Imperati*, from Baviolo, South Italy, the only species with a rose-coloured perianth; also a white variety of the same, first introduced by Dr. Lowe, who sent it to the late Rev. H. H. Crewe. Mr. Maw observed that the obesa form of *Corbularia*—not a distinct form—was characteristic of many, as of *C. nivalis*, both of larger and smaller kinds, *N. nanus*, found wild near Bewdley, Salop. Mr. Maw also showed specimens of a species of *Chionodoxa* from Crete, having a much smaller flower than *C. Lucilise*. Dr. Masters observed that the latter will degenerate in a wet soil so as to assume a diminished stature, which was, therefore, probably solely due to its habitat. A *Fritillaria* from Erzeroum, Armenia (chocolate-flowered), and which was figured in the *Botanical Magazine* with a yellow form from mountains near Smyrna; also a vernal form of *Colchicum* from the Dardanelles were exhibited by Mr. Maw.

Mr. G. F. Wilson exhibited a small species of *Primrose* which had come up amongst Himalayan seed, and several blossoms of seedlings of Scott Wilson, showing the retention of the blue tint, though exhibiting great variety of colours. Mr. W. D'Arcy Godolphin Osborne sent a plant of a white *Primrose* found wild near Biarritz. Though a common cultivated form it is probably rare in a wild state. It was growing in red clay. Colonel Clarke exhibited blossoms of a hybrid of *Primula ciliata* crossed by pollen of a dark alpine *Auricula*. The colour closely resembled the latter, but the corolla was very large, being quite half as large again as the *Auricula*, while the centre was of a deeper yellow. Colonel Clarke also showed a leaf of a hybrid between *Rheum palmatum* and the common garden *Rhubarb*, *R. undulatum*. Rev. G. Henslow exhibited a mauve-coloured bloom of an *Azalea* which had appeared on a shrub with nearly scarlet-coloured flowers. The foliage on the sport was much larger and more hairy than on the usual branch. Moreover, in the sport there was a tendency to doubling, but not in the normal flower.

A communication was read, giving details of Mr. Tait's and Mr. Barr's observations in North and South Portugal.

Corbularias.—Of these was found a large form, perhaps *conspicua* or *serotina*, in marshy ground, and in sandy woods of *Pinus maritima*, edging the marshes; there was a much dwarfed form, varying in colour from a rich orange to pale yellow, distinctly striped with greenish white; all probably of one species, but with variations, due to environment, as some of the larger kinds, planted in 1855 in a dry situation, have become reduced this year. On higher ground in North Portugal the *Corbularias* are small, with Rush-like, twisted, and drooping leaves; but at 2000 feet in the Gerez Mountains was *C. nivalis*, with erect leaves and small flowers, varying from a rich yellow to pale sulphur. In February a fine form, probably *C. obesa*, *Salisb.*, was found in Estremadura, at Montegil. Mr. Tait remarks upon the varying lengths of the styles in this species, and thinks that it is an unstable character for classificatory purposes. He notices—that has been already observed by others—a similar instability in the stamen of *N. triandrus*, an approximation towards heterostylism. It is rare, he adds, to find the style deep down in the Ajax section.

A small-flowered form of *Ajax*, transplanted in 1855, has now borne flowers equal in size to the larger form, the small size being attributed by Mr. Tait to poverty of soil. He notices great variation in the forms of the flowers representing *maximus*, *major*, and the *Tenby*, suggesting to Mr. Barr that these forms originally came from Portugal. Near Braga forms with the perianth paler than the crown, as in the English and Scotch wild form, were met with. *Ajax bicolor* occurred in abundance, and was the nearest approach to pl. 1187, *Botanical Magazine*. Mr. Barr has found *N. Johnstoni* in several localities in North Spain. *N. triandrus* is specially remarkable for the extraordinary variations in form of flower, foliage, size of bulb, &c., together with the curious trimorphism of the sexual organs. *N. triandrus* var. *concolor* was found in a few mountainous situations by Professor Henriques, and Mr. Tait identifies it with Parkinson's *N. juncifolius* *flore-luteo reflexo* (*Parad.*, p. 92), remarkable for its golden-yellow colour. *N. Jonquilla*, a remarkably large form, has flowered with Mr. Tait. Mr. Tait concludes his interesting communication with some remarks on hybrids, all of which are of a creamy-white colour when due to the natural crossing of pseudo-*N.* and *N. triandrus*. Other hybrids from Gerez are uniform in size, colour, &c., and partake of the features of both the parents, viz., *C. nivalis* and *N. triandrus*. He asks, Why are these hybrids so rare, and do they die out?

NOTES OF THE WEEK.

Narcissus Corbularia conspicuus.—We enclose a few blooms of *Narcissus Corbularia conspicuus*. We think it a good thing when established.—COLLINS BROS. AND GABRIEL.

* A very fine, large-flowered form of the Hoop Petticoat *NARCISSEUS*.—ED.

Curious Gloxinia.—I send you a curious *Gloxinia*, producing in addition to the usual flower two blooms at the bottom of the flowering stem. Is this unusual?—R. FAISBY.
* The *Gloxinia* sent had flowered in the usual way, and at the same time there were two blooms at the base of the flowering stem. This is not unusual.—ED.

Clematis indivisa lobata. This is a half-hardy climber, far less known and grown than its merits deserve. It differs from the typical form in having lobed leaves and larger flowers. It is generally distributed throughout the New Zealand islands, where it is said to festoon the trees on the skirts of the forests. In cultivation it proves to be a free-growing plant, and an abundant bloomer throughout the winter months, if planted out in the border of a cool greenhouse or conservatory in a mixture composed of about two parts loam and one of rough peat. The flowers are star-shaped, pure white, and sweet scented. We noted this variety blooming in the large *Gamellia* house in Mr. Laing's nursery at Forest Hill, where it has been a conspicuous object for some weeks.—G.

Streptosolon Jamesoni.—This very showy, free-flowering greenhouse plant, originally introduced by the Messrs. Veitch, nearly forty years ago, under the name of *Browallia*, is a native of Ecuador. It appears to have been lost, and was re-introduced some few years back. It is a compact growing plant, and readily forms a handsome specimen if struck from cuttings taken early in spring, and grown in the greenhouse or the open air in summer, producing dense racemes of flower, which are orange-yellow when they first open, but change when fully expanded to cinnabar-red. Although this has usually been considered a summer bloomer, we saw it laden with flowers, in the middle of March, in Mr. Laing's nursery at Forest Hill, forming a conspicuous object in the intermediate house.—G.

Royal Horticultural Society. Any honorary, foreign, or corresponding member of the society may obtain a copy of the Frost Report free of charge by applying to the secretary of the Royal Horticultural Society, South Kensington, S.W. Mr. George Maw, F.L.S., of Bentham, Kenley, has been elected a member of council vice Mr. A. B. Mitford, C.B., who has resigned. It has been decided to hold a Chrysanthemum show and conference on the 8th and 9th of November next. The idea of holding a conference on Grapes has been abandoned for this year. Arrangements will shortly be made

by which residents in the neighbourhood of the Royal Horticultural Society's gardens at Chiswick, who are not Fellows of the society, will be admitted to the gardens on easy terms.

Seedling Carnations.—I herewith enclose a bloom from one of my last year's seedling Carnations, which well shows the sportive character of these growing favourites. The seed from which the above came from was supposed to be white, and of the Tree section; whereas the habit and manner of flowering of this partake almost exactly of the border class, and, as you will see, the colour is nearly the exact counterpart of the old dark Clove, while the scent is quite as powerful. I was curious to measure it, when I found its circumference to be exactly 9 inches.—J. KNIGHT, *Epsom*.

* A fine large flower of a rich crimson-scarlet colour, the perfume very strong as in the old Clove. It does not split the calyx.—ED.

LAW.

OVERSEERS OF LEWISHAM I, H. J. COBB.

This was an application of the overseers for the payment of £2 11s. for rates in respect of his cottage and nursery grounds, Derby Villas, Forest Hill. Mr. Coxwell appeared for Mr. Cobb, and contended that after the decision Purser v. The Worthing Local Board, heard in the Divisional Court before Mr. Justice Day and Mr. Justice Willis, Mr. Cobb could be assessed in respect of the nursery grounds at a quarter only, but as regards the cottage occupied by him at the full value. This was opposed by Mr. Clutter, the collector, on the grounds that there was one assessment only. Mr. Montague Williams, after considering, said that there should be separate assessments for the land and cottage, and having reference to the Inhabited House Duty Act of 1881, adjourned the case to allow the parties to come to terms.

Easter decorations.—One of the most effective of the many decorations made in the beautiful church here has this year been of the fine deep scarlet *Geranium Henri Jacoby*. This has been grown largely in 6 inch and 7-inch pots for rooms and cut flowers, for which I find it most useful. Also for mixing in groups of plants in chancel of church or elsewhere, with Palms, Callas, *Cytisus*, and *Spiraeas*, this beautiful *Geranium* has no equal. On Easter day, another subject used largely here for vases was branches in flower of the fragrant *Stantonia latifolia*. Long branches cut the night before and placed in pans of water will stand without flagging during the next day in tins of wet sand in the church. Wherever required, we have a plant of the *Stantonia* planted out and trained up the pillars of the conservatory in the centre of the glass range at this place, and at this time of the year its delicious scent pervades the place. The church here, lately redecorated by Mr. Harold Willoughby, was last Sunday unusually bright with flowers.—BAILEY WADDIS, *Birdsall Gardens, York*.

We regret to hear of the death of M. Jules Vallerand, a very amiable and excellent French gardener, who raised most of the pretty *Gloxinias* that have been added to our gardens during the last twenty years or so. He was the first we saw in possession of the beautiful delicately spotted kinds which he raised near Bourguival.

ANSWERS TO CORRESPONDENTS.

One Arctostaphylos to Know.—We can see nothing wrong with the Peach flowers. We have examined several and find that the fruit has set.

Names of plants.—*B. J., Guildford.* 1, *Lycaste Harrisoniae*; 2, a form very near the variety *eburnea*.—*A. S.*—*Arabis alba*.—*J. H. P.*—*Narcissus cyclamineus*.—*A. McD., Perth.*—*Auricula*, very large, but somewhat rough; paste much cracked.—*J. C., Colchester.*—1, *Diplopappus chrysophylla*; 2, *Cupressus Lawsoniana*; 3, apparently a variety of *Abies excelsa*, specimen insufficient without description of habit; 4, *Taxus baccata*, aff. *pendulous*, variety *Dovastonii*.—*H. J. N., Bishops Castle.*—Specimen bloom much dried up; appeared to be an ordinary coloured *Primrose* of little distinctness of character.—*M. Facello.*—Your *Adiantum* appears identical with *A. Ludemannianum*. The *Pteris* is certainly broader than the typical *P. tremula*, but from a single form we are unable to judge if the plant merits a varietal distinction.—*D. D., Sittingbourne.*—1, *Odontoglossum gloriosum*; 2, *Vanda tricolor formosa*; 3, *V. unguis*; 4, *V. tricolor insignis*; 5, *Cymbidium aloifolium*.

WOODS & FORESTS.

"YORKSHIREMAN."

PINUS PATULA.

HAVING a long time ago had some experience of this Mexican Pine, I can endorse all that Mr. Webster (p. 337) says of its beauty, but must confess that I am agreeably surprised to hear that it is hardy. Amongst other reputed tender varieties, in the year 1860 I found a very fine tree favourably planted at Eastnor, but that fatal winter killed it. At a gentleman's place, much warmer and better sheltered, a short distance away I saw a much finer tree than ours, but that also was destroyed, and I arrived at the conclusion that it was too tender for the west midlands. In Cornwall and Devon it may do well, but those two counties no more represent our English climate than the first Rose ushers in the summer; consequently, much as all lovers of Conifers may wish to plant a tree whose lovely leaves represent thousands of skeins of silk, I fear we must search far and wide through the average counties of England before we meet with a specimen equal to that at Penarrow. Mr. Webster, however, is a great authority, and his article should have weight with the trade who, for reasons well known to themselves and planters generally, have dropped *P. patula* out of their lists, and I sincerely hope they will soon be in a position to again offer it to the public. If found too tender for cold and exposed districts, the owners of large conservatories and winter gardens might grow it for years, as they now grow the Norfolk Island *Araucarias* in tubs for the decoration of their terraces through the summer. The habit of the tree, it is true, is rather against its being crowded in a cold house in winter, but a specimen nevertheless confined to the pyramidal form and 20 feet or more in height would form a charming novelty. The *Daerydiums*, the *Callitris*, the *Fitzroyas*, the *Cunninghamias*, and all the tender *Araucarias* do well in moderate-sized tubs, and this soft and lovely Pine would go well with any of them. Another graceful Pine with us—the hardiest of the Mexican race—is *P. Montezumae*. This, unfortunately, is seldom met with, but planters, I think, in all sheltered places might give it a trial, for certainly it is much hardier than *P. patula*. Tender Conifers generally with us are now beginning to show the effect of the past protracted winter. Some of our beautiful *Pinus insignis*, so terribly mutilated by the snow, are slightly browned, but not seriously. The parts suddenly exposed by the loss of large branches have suffered most, and the piercing north wind which has been blowing for some days is making its mark, as it follows nearly in the line of the snowstorm. *Pinus Ayacahuite*, or *Don Pedro*, another of Hartweg's introductions from the mountains in Northern Mexico, is slightly tinged, not on the north, as one might have expected, but on the south side. Next to *P. patula* this is one of the softest and most graceful Pines I am acquainted with, but being decidedly tender, I cannot recommend it to inland planters. Here it is planted on the south side of a limestone knoll 450 feet above sea level, upon which *Pinus insignis* and *Abies Pindrow* pass through the sharpest winters without losing an old leaf or a young spring growth.

W. C.

with descriptions of the various Planes, so as to settle the knotty points in their nomenclature. All the large Plane trees in and about London are supposed to be the *Platanus occidentalis* or American Plane, and the reason why it is considered tenderer than the Oriental Plane is because it not infrequently suffers severely from having its young leaves and fresh growth half killed by late frosts in May, particularly after mild winters and early springs. In all other respects it is as hardy as the Oriental Plane. The Maple-leaved or Spanish Plane (*P. acerifolia*) has the same spreading habit and fruit as the Oriental Plane, and never grows to so great a height as the American Plane. The Oriental Plane is unquestionably the best of all the Planes, both for shade and handsome foliage; but it is, not nearly so rapid a grower as the American Plane, particularly when young. It forms a round and rather dense-headed tree, seldom exceeding 60 feet in height, with a comparatively short, but massive stem, which soon divides into several robust arms, the lower ones of which are the largest, spreading horizontally to a very considerable distance. The greatest difficulty in the way of planting Oriental Planes—as trees for shade along a public thoroughfare—is in getting them with stems sufficiently tall to raise, when full grown, their lower and wider-spreading branches high enough so as not to interfere with vehicles passing under them.—A. L. S.

THE DROPMORE DOUGLAS FIR.

"W. G." tells us (p. 289) that the Douglas Fir at Dropmore "is probably the finest in Europe." It may, perhaps, be one of the tallest in Europe, but as regards size of stem it can bear no comparison with several of its kind even in our own little island, as the following measurements, taken to-day of a couple out of many specimens at Penrhyn, will clearly show:—

No. 1—Girth of stem at 3 feet up, 13 feet 5½ inches.
Do. 5 " 11 " 3 "
Do. 12 " 9 " 4 "

Twenty-four feet in length of the butt contains exactly 131 feet of wood.

No. 2—Girth of stem at 3 feet up, 11 feet 9 inches.
Do. 21 " 8 " 4 "

Forty-two feet in length of the stem contains 217 feet of excellent clean timber. Both specimens are feathered to the ground with bright, healthy foliage, the diameter of spread of branches being from 50 feet to 60 feet. That these fine trees are not what is termed "carrot-shaped," but of gradual taper throughout, will be easily seen from the stem-measurements at 12 feet and 21 feet respectively.

Now, as the Dropmore tree is only about 10 feet in girth at a yard from the ground (3 feet 8½ inches less than the Penrhyn tree), it would certainly look very small indeed if placed beside the colossal giants whose measurements are given above. Allowing the Dropmore tree to be 4 feet in girth at 50 feet from the ground, its total contents would only reach about 100 feet—not half that of the largest tree at Penrhyn. It may be well also to state that, unlike the Dropmore Douglas Fir, those of Penrhyn have had no coddling nor "loads of soil placed around their roots," and no kind hand to remove at the proper time rival leaders nor correct ungainly side branches. One of the branches of No. 1 is more than half as large as the Dropmore tree, being exactly 6 feet in girth.

I had an interview the other day with the old man who planted these trees, but, alas! age had brought its infirmities, and "the memory was not so good as it used to be." He remembered well, however, having, with another man, carried five plants in pots from the flower garden and placing them in their present position. (This, I believe, from careful investigation, was fifty-one years ago, but as I have no direct evidence, these figures must only be taken for what they are worth.)

The Hon. Mark Rolle, in a letter received this morning, likewise informs me that in his pinetum at Bicton, one of the Douglas Firs measures 10 feet 6 inches at 5 feet up. This is even a much larger stem than that of the Dropmore tree. If I remember rightly, the Dropmore Douglas Fir is not a perfect

specimen, for many of its branches were broken off during a snowstorm some years ago. How does it come that the Dropmore tree was planted in 1828 ("W. G.," p. 289), for the seeds "were only received by Mr. Frost from the late Lord Grenville early in December, 1827?" Was it planted in its present position as a nine-months-old seedling? "W. G." tells us further regarding the Douglas Fir that, "as a rule, it is not a good tree for sandy soils," but it may surprise him to know that this is the very class of soil which has produced the above unique specimens. On light alluvial deposit we have many very large trees, and on dampish loam likewise.

The above is written with the sole object of again correcting the oft-repeated mistake regarding the Dropmore Douglas Fir being the largest of its kind in this country. It may, as before stated, be one of the tallest (I am getting up a list of the tallest, and will, I hope, ere long be able to speak with certainty on this matter), but in point of size it can bear no comparison with many others; and height without thickness can hardly claim for its possessor the right of being recorded as perhaps the finest of its kind.

A. D. WEBSTER.

Penrhyn Castle, North Wales.

ROADS ACROSS PEAT BOGS.

FAGOTS are often used for forming the foundation of roads across bogs, but though an old plan, I do not think it is the best possible, as by the pressure of traffic the water of the bog is forced up through the fagots, and the stones forming the covering will sometimes fall through on to the ground below.

The first operation in making a road over a peat bog is to make large open drains at a considerable distance from, and parallel to, the intended site of the road on each side. When, by the operation of these drains, the surface has somewhat subsided from the escape of the water held by the peat soil, other drains should be made along each side of the intended road. The whole of the peat excavated from the drains should be thoroughly dried, as for fuel, and when the surface of the site of the road has become firm, any hollows should be filled up with the dried peat, and the unbroken surface covered to a depth of several inches with it—first with pieces the size of bricks, and then with small pieces the size of hens' eggs—until a convex form of cross-section is attained. Some will suppose that this use of peat is very much like restoring the surface to its original condition, but a remarkable property of peat is, that when it has been thoroughly dried, it will never again absorb water, and this renders this earth, on being completely deprived of water, an excellent material for forming the foundation of roads over bogs. When covered with dried peat the road may be spread with broken stones in the same manner as any other road.

Roads made upon peat bogs in the above manner are remarkably pleasant to travel upon, and, without sensible increase to the force of traction in the draught of loads, of all others the most durable, arising from a degree of elasticity possessed by no other description of soil. I may say that, whilst a road made upon a peat bog is the most durable, that made upon rock is the least so, and the deficiency of durability is in proportion to the hardness of the rock; the expense of maintenance will thus be much less for the former than for the latter.

When a road is carried over a morass that cannot be thoroughly drained, the soil should on no account be removed, but the surface should be kept entire, and any hollows in it should be filled up with material to be obtained elsewhere than from the site of the road. The surface should then be covered to a depth of several inches with concrete, composed of six parts, by measure, of gravel and one part of Portland cement, before the application of the broken-stone covering.

A. T. PATERSON.

A dry spring. The following account of the rainfall in North Leeds for the early months of the last four years, may be of interest to some of your readers. It will be seen that the total for the first three months this year is 1½ inches below the

Plane trees in London.—There seems to be a good deal of confusion, especially in nurseries, with regard to the names of the various Planes now grown in this country, and it would be of great service if some one of authority would give us a good account,

average of the corresponding periods in the preceding three years:—

	1884.	1885.	1886.	1887.
	Inches.	Inches.	Inches.	Inches.
January ..	3.18	1.49	3.54	2.42
February ..	2.12	2.11	.66	.61

THINNING PLANTATIONS.

HAVING quite recently had some almost painful experiences of the difficulties of selling at a fair price some large hedgerow Oaks netting from 100 feet to 150 feet, owing to their coarseness, I have been specially interested in "Wilts" and "Yorkshireman's" remarks on thinning (see p. 291). The above experience has also sent me to the surveying and measurement of numbers of park trees more or less isolated. Were all their boughs timber, and their gross bulk saleable by weight as such, they would doubtless yield a good return. But as this cannot be, the waste in such trees can only be described as reckless. In many such trees not a third of the gross bulk or weight is saleable for useful timber, while it takes a good clean tree to yield a half of its gross weight as useful and saleable timber. It is not simply the sheer waste involved in the far-reaching boughs and the multitudes of ramifying branches, though this is enormous, for if some of them reach timber size they only command a half or a third the price of bole timber—but it is the serious deterioration as well as the reduction of the amount of the latter. Coarse timber is a drug in every market, while fine, clean, smooth timber of almost any sort sells freely. Reasoning with a large timber merchant on the enormous difference of his offers for the two sorts, he replied, "We can never tell what we may find beneath these knots or burrs from which branches have been removed. The timber may be fairly sound, but more likely it will prove worthless. To buy such timber is quite a lottery, and our prices must be regulated by the certainty of many blanks." Thick planting, natural pruning, group or plantation planting, are the sure and certain modes of growing fine, clean-stemmed, long-boled timber. Upon this nearly all practical writers are agreed. But no sooner do we leave those general principles and descend to particular instances, than we differ widely. With a view of inducing greater uniformity of practice, might I invite "Yorkshireman," "Wilts," and other experienced foresters to give the average distances from planting to felling, or, say, for a period of sixty years, for plantations of different timber trees, as Oak, Ash, Elm, and Spanish Chestnut, Sycamore, Walnut, Larch, Spruce, Scotch, &c.? Of course the distances would only be approximate, and would be considerably modified in practice by soil, site, shelter, exposure, &c. The leading ideas in determining the distances at different periods would be profit, and self-pruning of the trees, and the maximum benefit from that stem-protection and fostering ensured by the overhead canopy of leaves, so graphically described by "Yorkshireman" in THE GARDEN, page 291.

CALEDONICUS.

VARIETIES OF THE ASH.

THE common Ash (*Fraxinus excelsior*) and several of the North American kinds rank high as timber-producing trees, their wood, owing to its elasticity, being much sought after where strength and toughness are wanted. Apart, however, from their value in this respect, the different forms afford plenty of scope to the planter, some being large, noble-looking trees, others comparatively small, and a few singularly grotesque.

The recognised varieties of the common Ash are many, some of the more distinct being the weeping kind (*pendula*), so often employed for forming

arhous; of this there is also a golden form (*pendula aurea*), the bark of which is bright yellow, but in other respects, except being of somewhat weaker growth, it resembles the common Weeping Ash. Another kind (*heterophylla*) is remarkable on account of the absence of leaflets, and instead of one large, simple, deeply serrated leaf, it forms a tree nearly as vigorous as the common kind, and is often known by the name of one-leaved Ash (*monophylla*), certainly a better name than *heterophylla*, the leaves being seldom variable. Of this there is a form in which the leaf is deeply slashed instead of serrated. The Cockscomb Ash (*F. excelsior cristata*) has often a large proportion of the shoots curiously fasciated, especially at the points, where they spread out in a Cockscomb-like manner. This is but a slow-growing tree, and frequently some of the branches die off without any apparent reason. A dwarf, bushy kind (*F. excelsior globosa*) assumes the shape of a small round bush, and when grafted standard high has a mop-like appearance.

Other varieties, in addition to those just mentioned, are *crispa*, a dwarf form with very deep green and much-curved leaves, often encircling the stem; the gold and silver variegated, neither of which are very effective when exposed to wind and sun; *aurea* and *jaspea*, with bark yellow and striped; *angustifolia*, a kind in which the ordinary leaflets are reduced to mere filaments; and *verrucosa*, a variety with rough and verrucose bark.

A.

COMMON USES OF WOODS.

MORE conversant with the living trees, their characters and habits, than with their uses, tree-planters may perhaps have little interest in any detail of a subject somewhat outside their vocation; but apart from the picturesque or garden uses of trees, there is some importance to be attached to the uses to which trees can be applied after they have been cut down and manufactured for use. The Oak is the grandest and most historical of all our forest trees. It has long been associated with our national defence as the chief element in shipbuilding, but harder and sterner iron has robbed the Oak of this sentimental element, and the glory of our "wooden walls" of Old England has for ever departed. Now the Oak furnishes the builder with the best material for door posts; wheelwrights find in it the best wood for the bottoms of carts and wagons, and it makes the best of all wood fencing. Pollarded Oak is a valuable element in the making of furniture, the knotted and intricately designed surface making the most elegant of veneering for what is known as Oak suites.

To the Elm is attached a melancholy and weird interest, inasmuch as it forms the small but solid enclosure in which dead humanity is placed. For commoner uses it is valuable for the making of wheel-stocks, as it is not so liable to split and enables the spokes to be fixed with any amount of force. It also enters into the construction of wide felloes, such as are employed in wheels for farm carts and heavy wagons. It forms a prominent element in the construction of that useful vehicle, the wheelbarrow, and the bodies of carts. It also enters into the construction of heavy bellows as boards, and in the form of seats to Windsor chairs it furnishes frequent means of rest to exhausted humanity.

Ash is a very valuable timber, and is fast getting scarce. It is not one of the favoured ornamental timbers, and therefore is now much less planted than formerly. A dearth of Ash timber would be productive of great inconvenience to many trades. Wheelwrights employ Ash largely in the construction of carts and carriages; it forms the best material for shafts, and is widely employed in the making of all kinds of tool handles, especially those used in gardening, such as spades, forks, shovels, hoes, &c. In a less interesting way it is used for butchers' blocks, and many other common purposes.

The Beech is a noble tree in life, perhaps the most beautiful and decorative of all forest trees, but its uses in domestic life are not so varied as are those of some other woods. Beech is the chief constituent in the making of the elegant cane-bottomed chairs found in the parlours of the poorer classes; it is useful for gun stocks, saddle trees in heavy harness,

wheel felloes, and many of the lesser tool handles. Hornbeam is closely allied to the Beech in life, but its uses are even less varied. Owing to its peculiar toughness it is often employed as cogs in mill-gearing, and in the construction of bearings, as its wear is regular and even. In another direction it administers to the employment of a section of the community—it makes the best of skittle-pins.

The Sycamore furnishes a peculiarly white, smooth wood, free from grain, and is used for the formation of curtain rings, butter churns, and prints; for this latter purpose it is valuable, as it enables a finer design to be cut than does any other wood of home growth.

The Lime in life is for a time the means of diffusing sweet odours and sweet sounds when the myriads of bees are seeking for its honey treasures. After death it enters into the production of other harmonies, as it is largely employed in pianofortes, where its value is seen in a comparative immunity from those fluctuations of contraction and expansion peculiar to most woods. Shoemakers find it also the most suitable material for their cutting boards, as it does not blunt the fine edges of their knives. The Spanish Chestnut, also, is largely employed in the formation of sides for pianos, and at times is elevated as signboards. Formerly the Chestnut was largely employed in the construction of principals and rafters for open-roof churches, and is occasionally degraded to the common uses of posts and rails for fencing. The grand-looking Horse Chestnut does not furnish a specially valuable timber, its wood being occasionally employed in the making of brushes. The Birch, also, is employed in brush manufacture, and in the formation of bat blocks for hatters; also in the production of toys. In this way the tree becomes a source of pleasure to infantile life and a terror to breeched boyhood.

The Fir tribes are productive of noble trees, but the timber is not of a specially useful kind. It is too soft, as indeed is the case with all wood that is the product of quick growth. Both the Spruce and Scotch Firs are of kindred quality, and are commonly employed in the construction of outhouses and sheds, or rafters to barns, and for temporary posts and rails, but, except where kept very dry, having only slight powers of endurance. If the Pine tribes are to furnish the trees of the future, our prosperity will find that in the matter of useful woods we have left them but an indifferent legacy. Larch is superior in enduring quality to the evergreen Firs, and is therefore largely used as railway fencing and for ordinary estate and farm purposes. Yew wood is valuable when employed for veneering. It also makes most enduring gateposts. The Maple is employed in the turning of bowls, and the Bird's eye Maple for the manufacture of furniture. Acacia is very hard and durable, and makes good ladder rounds and bottoms to carts. The Poplars cut out good weather boarding, and are also employed in the formation of railway brakes, as the wood is woolly and tenacious. Walnut is valuable for the manufacture of furniture and gun-stocks; Apple is used for wheel-cogs, and the hard stems of the Crab for beetle heads. Pear will dye black, and resemble ebony, and makes good walking-sticks. The Willow is famous for the production of cricket bats. The Plum produces shuttles for weaving, and the Cherry is used in the making of chairs. These are but a few of the many uses to which home-raised woods are put, but for all our chief constructive purposes we give the preference to foreign timber.

A. D.

The sweet-scented Laburnum.—This fine form of the common Laburnum should be more frequently grown. Probably many are not aware that there is a variety of Laburnum (*Cytisus Laburnum fragrans*) with very sweet-scented flowers. Good varieties of ever popular trees like the Laburnum are doubly valuable, as we know they are sure to thrive with us.—J. O.

Ilex heterophylla magna.—This is one of the finest of all the green-leaved Hollies—strong in growth, and with foliage reminding one of that of a well-grown Bay tree. This and *Ilex balearica nigrescens* are perhaps the finest green-leaved kinds. The last-named is a remarkably vigorous and ornamental Holly.—A. L.

No. 805. SATURDAY, April 23, 1887. Vol. XXXI.

"This is an Art
Which does mend Nature: change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

FRUIT GARDEN.

W. COLEMAN.

AN INVALUABLE LATE WHITE GRAPE.
MRS. PEARSON.—More than once I have expressed an opinion that Mrs. Pearson would prove one of our best late hanging Grapes, but until this season I have not tested it to its utmost. Now, however, I am in a position to say it has not only exceeded my expectations, but under generous treatment it will keep fresh and plump in the Grape room certainly up to the middle of April. When sending off a quantity of Grapes the third week in December I decided upon leaving a bunch to thoroughly prove its keeping properties, and now, this 15th day of April, it hangs apparently unchanged and the flavour is excellent. Until recently the majority of Grape growers have been impressed by the idea that white Grapes should be worked on varieties of kindred race and colour; but this is a fallacy, as the Vine in question was grafted on a side shoot of a Gros Colmar, and although Mrs. Pearson comes first into flower the two run well side by side, and the flavour of Mrs. Pearson is in no way depreciated by the stock. Where the Muscat of Alexandria is grown in quantity and well, consumers do not wish for anything better; but few, I believe, since Mr. Tilyard some years ago brought out his magnificent examples late in March, have succeeded in keeping the king of Grapes beyond, if up to that period. Therefore a white Grape that will overlap the Muscat, if only by a month, is worthy of general cultivation.

On reference to our best of all standard works, "Vines and Vine Culture," by Barron, we find it faithfully described as a round white Muscat; late in ripening, hanging late, and keeping well; quality first-class.

Vine.—Very strong and vigorous in growth, the wood ripening freely; fruitful. Leaves.—Medium-sized, thick and leathery, deeply lobed and toothed, with reddish petioles and venation. Fruit.—Bunches above medium size, with large shoulders, tapering, on very strong footstalks, freely set. Berries nearly round. Skin.—Thick or leathery, deep green, assuming an amber tinge when quite ripe. Flesh thick or firm, juicy, sweet, and with a strong, very pleasant Muscat flavour. History.—Raised by Mr. Pearson from Black Alicante crossed with Ferdinand de Lesseps. First-class certificate 1874. Cultural notes.—Requires fully more heat and longer time to ripen its fruit than Muscat of Alexandria.

Surely this is a good all-round character, but why it has not come into very general cultivation it is difficult to say, and, assuming that it does take as much heat as the Muscat, why, let it be grown with the Muscat, and I venture to say no one will be disappointed. It is not, however, such a difficult Grape to manage, as it will set freely with Hamburgs, and for this reason a Vine or Vines may be planted or worked in second early houses that are started not later than the middle of February. A great noise is made periodically about certain stocks being unsuitable for certain varieties, but, as Mr. Castle and others have lately shown, there is nothing in it; and when we consider that many of our popular modern black and white sorts have been produced by parents of opposite colour, habit and season, we quickly arrive at the conclusion that a sound, healthy stock well planted in a sound, healthy border may safely be selected for any variety. Here

we have Mrs. Pearson doing well on Gros Colmar, to which naturally we give the whole of the summer. In a second early viney the finest cane of Gros Maroc I ever grew was grafted on a healthy young Grizzly Frontignan. I do not, as a matter of course, recommend these extremes, but merely report them, if to answer no other purpose, certainly to show that the Vine is less fastidious than many people imagine. Indeed, I question if any other fruit is so thoroughly accommodating, for if we take the Apple or the Pear we find some varieties doing well, whilst others positively refuse to grow on dwarfing stocks. Peaches and Nectarines, again, have their foibles, and so have Apricots, as we find the majority succeeding best on the Mussel Plum, whilst a few prefer the Brompton.

FRUIT TREES AS ORNAMENTAL SUBJECTS.

Why should not fruit trees be grown more for their beauty alone? Take the Peach, for instance; everyone is charmed with it when in full bloom, but some might say we cultivate the Peach and other fruit trees for the fruit alone, and not the flowers. True, but are they not worthy of it, for when we consider the flowering charms of a greater portion of our fruit trees, is it not surprising that they are not more grown for their beauty alone?

In early spring we may reap a harvest of beauty from nearly all hardy fruit trees, such as Apricots, Peaches, Plums, Cherries, Almonds, Apples, and Pears, as they are all more or less ornamental—the double-flowering Peach, Cherry, and Almond being particularly so, and all of these trees should be planted more abundantly than they are, for in the spring no shrubs are more attractive. They may be grown in any form, bush, pyramid, or standard, and to various sizes; and when flowering as standards in the open borders they form conspicuous objects. A little attention, however, is required as regards keeping them well supplied with young wood, as upon this the flowers are produced. They should also be planted in good soil to induce them to make plenty of growth. The double-flowering varieties of the Peach, Cherry, and Almond also force well, and a good show of their beautiful bloom may be obtained from Christmas up to the present time. They are of easy cultivation, and well deserve a place in the conservatory amongst other flowering plants. When grown for this purpose they should have the same care in cultivation as when grown for fruit. Young maiden plants may be obtained from the nursery; these should be potted in the autumn and placed in a cool house until required for forcing, when they should be removed to a warm house where they will soon flower, after which they should be placed in the cooler quarters, where they will continue in bloom for a long time. After flowering the plants should not be placed outside all at once, as is the usual practice with subjects that have been forced. They should be kept under glass and well attended to in the way of watering and keeping free from red spider, aphids, &c., until the summer, when they may be gradually hardened off and finally placed out of doors in a position where they can have the full rays of the sun so as to thoroughly ripen their wood. There is a scarlet variety of the double-flowering Peach, likewise many other deep coloured varieties, which make a lovely contrast with the white flowers of the Almond and Cherry.

As is well known, the common wild Cherry is very attractive when in flower. I have seen enormous trees of it one mass of beautiful white

bloom. The wild Crab is also very attractive. Many trees of this sort would be found well worth the trouble if planted in any open space in pleasure grounds or by the side of woodland walks, instead of the worthless subjects which now too often occupy such places.

C. COLLINS.

HARDINESS OF STRAWBERRY PLANTS.

UNLESS all the varieties grown in any particular district are planted out together on an open piece of ground, and uniform preparation and treatment are accorded to all, it is neither fair to the plants nor to their raisers to say one is harder than another. These remarks apply specially to new varieties, to which gardeners generally devote a little extra care both as regards fresh soil and shelter, and for this reason Pauline should neither be praised nor condemned until it has withstood the vicissitudes of drought as well as frost by the side of our well-tried standard varieties. Here Pauline has stood remarkably well, but under what conditions? My first set of plants was planted out on a south border, and, being anxious to make all the stock possible, fresh soils of turf, 2 inches thick and 1 foot in width, were laid alongside the rows last August. Upon these the first set of runners were firmly pegged, but instead of pinching out the points, these were allowed to extend, and in due time a second set was secured, and so on until the end of the season. These plants, it is hardly necessary to say, never felt the want of water, and their condition throughout the winter has been quite satisfactory. They do not, however, look better than Paxton, President, La Grosse, and others planted out in August in the open quarters. Like Mr. Douglas and the majority of private growers, I have tried many varieties, and make large plantations annually upon the open quarters. All are treated alike, and some succeed better than others, but once fairly started they stand or fall without the aid of coddling or nursing. We grow a goodly breadth of late sorts on north borders; the walls are not more than 10 feet in height, consequently they receive plenty of light, a fair amount of sun, and although they sometimes suffer from an excess of wet, this spring they are looking quite as well as kindred kinds on open quarters. I do not object to old plantations losing most of their leaves, as this is a fair sign that the crowns are well ripened. Moreover, such plants soon throw up fresh leaves and produce flowers in great profusion. Frogmore Late Pine and Loxford Hall Seedling winter very well with me; but I am obliged to raise the strongest young plants I can secure every year, otherwise they go off during the summer. The old favourite Sir Charles Napier is least satisfactory, and for some years I have given it up; but if any distant reader has a few good plants to spare, I shall most thankfully accept them. W. COLEMAN.

I have been anxious for some time to know how Strawberries outdoors have fared, and after reading Mr. Gilbert's letter, I have to-day particularly noticed the several varieties growing here. Elton Pines are without a green leaf; British Queen, though not so bad, looks very sickly; Vicountesse Hélicart de Thury is the best of all; Loxford Hall Seedling is very much cut up, as is also Paxton's King of the Earlies; Pauline, planted in a very exposed position, looks promising. I never remember seeing, not only the Strawberries, but vegetation generally so cut up. Wind north and north-east, with up to 16° of frost on Good Friday, is enough to startle the most able man.—STEPHEN CASTLE.

Notes on the Pepino (*Cucumis sativus*).—The taste of the fruit varies with the locality, and I must here reiterate that the hotter the place the poorer the taste of the Pepino. Those which I raised under glass never came up in flavour and acid to the fruit raised in the open ground. In fact, both were decidedly wanting. Without the acid the fruit is comparatively valueless, as it is this remarkable acid—remarkable by its property of allaying the thirst—which gives the fruit its great value. In eating the fruit it is necessary first to peel it, as the skin contains a very bitter principle, or perhaps a

rather pungent one. As the Pepino ripens in the Central American highlands, where the average temperature during the ripening season is about 72° Fahr., it certainly ranks as one of the most valuable fruits of the country, and is so considered by both natives and foreigners. It is, however, not to be expected that the Pepino will prove equally good everywhere, but it will find its choice location just as nearly every other fruit known. A plant and fruit somewhat analogous to the Pepino as regards climate and other conditions is the "Curuba," from the highlands of Ecuador and Bogota. It is a Passion Vine, bearing a fruit there considered the finest of all fruits, and is generally commented upon by all travellers. The seed of this was first introduced by me to Central America, and from there brought to California. The Vine is tolerably hardy, having here in Fresno stood uninjured, except as regards the very tender tips, a temperature of 26° Fahr., northern exposure. I have great hopes in this fruit for California and the south, and perhaps also as a greenhouse Vine. It is entirely distinct from *P. granadilla* and *edulis*. The scientific name I do not know.—GUSTAV EISEN, in *Gardeners' Monthly*.

GRAFTING AND INARCHING VINES.

MR. CASTLE evidently firmly believes in the possibility of improving the quality of an inferior sort by grafting or inarching it on to a variety of superior excellence, this being altogether at variance with my experience as given on pages 208 and 209. The favourite stock—the Muscat of Alexandria—I have not had much experience with for grafting purposes, for the simple reason that I have never practised in a garden where any of the latter could well be spared. For home consumption the Muscat of Alexandria has no equal, and, as far as my experience goes, no other Grape realises such high prices in the market, say to the end of February, and always supposing the samples are good. Being one of the most vigorous growers without approaching grossness, it is undoubtedly well suited as a stock for any other variety, and as Mr. Castle finds Gros Colmar a more profitable variety, he acts wisely in utilising it as a stock for the latter. As he is careful to point out, his Grapes are grown for the markets, which is a very different matter to growing for employers who insist upon having Grapes of high quality. Thanks to the courtesy of Mr. Castle, I have recently had an opportunity of tasting Gros Colmar cut from rods inarched on the Muscat of Alexandria stock, and readily admit they were much above the average quality of this variety, but I venture to assert that the improvement effected is owing to two causes, viz., superior culture and good preservation. Unfortunately, we used the last of ours early in March, and therefore could not compare them with Mr. Castle's, but others beside myself who both tasted the last of our Gros Colmar cut from Vines on their own roots and Mr. Castle's productions arrived at the conclusion that there was not much to be said in favour of the latter. The conclusion I have arrived at is, that Gros Colmar is not in season or at its best much before March, and both private and market growers will do well to keep them as much as possible to that time of the year. Mr. Castle also keeps the Alicante in good condition and the flavour is good, but as a marketable variety it compares most unfavourably with Gros Colmar. I hope to have good bunches of Gros Marce on rods inarched and otherwise in three different houses—early, mid-season, and late—and shall be agreeably surprised if it is really good to eat in either case. I would much like to taste berries of this variety at all approaching in quality those of Gros Colmar kindly sent me by Mr. Castle.

SHANKING CURED BY GRAFTING.—Grafting, or inarching, Mr. Castle considers a partial remedy for shanking, and to a certain extent he may be right in his surmise. In reality, the mere fact of adding a fresh variety to the stock has nothing to do with it, but a new rod, whether from a graft or laid in from the old Vine, may safely be credited with the improvement effected. If called upon at the present time to prevent shanking, more especially on old Vines, my first proceeding would be to lay in young rods from the base, and in some cases or

where the Vines were weakly, a second one from near the middle of the old rods. These being duly stopped when they have reached their prescribed distances, all laterals and sub-laterals being also stopped at the first joint, taking care to well expose both the foliage and wood to plenty of light and air, we should have good rods for fruiting next year, and an autumn renovation of the border would complete the cure. In very many instances, newly planted Vines grow much too strongly the first two or three years, too large or too rich borders being principally to blame for this. The consequences of this are rods much too pithy, and as the pith is certain to shrink eventually, a contraction of the wood and an interruption of the necessary free flow of sap follows. In this state, if heavily cropped, shanking is the natural result. Innumerable rods are much injured by the time-honoured, but most unwise, practice of skimming, scraping, and plastering over with some strong compound, this being done under the impression that it is impossible to keep them clean during the growing season without it. Vines thus treated never swell properly; on the contrary, they appear to get smaller, but unless they continue to enlarge in a healthy manner, shanking will be brought about. Let me advise all who have charge of such Vines to commence their renovation by at once laying in young rods, or if it is desirable to change the variety, to graft or inarch them with more valuable sorts. Young or inarched rods will communicate some of their vigour to the stock or old growth immediately below them, others besides Mr. Castle being well aware that the flow of sap may easily be reversed. We have cut Grapes below the union of the scion and stock, or on the lower portion of the former, and these were perfected entirely by sap that descended to them.

W. IGGULDEN.

Diseased Vine leaves.—I send you leaves of a Vine and I ask your opinion. The Vine is a Muscat of Alexandria with two rods. Last year it perfected eighteen or twenty fair-sized bunches. The temperature, 75°, with sun heat, and about 55° at night (slight variation according to weather)—not under. In the same house are two other Vines, Muscat Hamburg and Mrs. Pince. These also did and are doing well now. The house had neither mildew, spider, nor thrips. The wood ripened well, had little pith, and was very firm. There are inside and outside borders drained and apparently in a satisfactory condition.—IVYBRIDGE.

* * Muscat Vine leaves deficient in chlorophyll. This deficiency is sometimes the result of an improperly high temperature, sluggish root action, and a diminished supply of light and fresh air; but this is not your case, as you state the minimum temperature of your vinery is 55°, the maximum 75° from sun heat. Again, you say that Muscat Hamburg and Mrs. Pince Muscat, two comparatively hardy Vines in the same house, are looking well. It is fortunate that these facts have been mentioned, as the cause of failure is plainly due to want of heat and probably an insufficient supply of fresh air. If the temperature to which a growing plant is exposed is not lowered so much as to destroy it, but just reduced to that point within which it will continue to live, the plant is brought, by the absence of a sufficient exciting cause, into a condition similar to that produced by over-excitement. It absorbs food from the earth and air, but it cannot assimilate it: its tissue grows, but is not solidified by the incorporation of assimilated matter; aqueous particles accumulate in the interior, a general yellowness ensues, partly from the want of a sufficient power of decomposing carbonic acid, and partly from the inability to decompose the water collected in the interior. Muscats in full leaf exposed to a temperature of 55° through the night are brought to the condition which does not kill, but being unable to decompose carbonic acid and exhale oxygen, the foliage becomes thin, flabby, and destitute of healthy colour and substance. Gradually raise the temperature of your house to 65° at night and 80° by day, allow fresh laterals to grow freely, give a chink of air through the night, shut it off at the morning syringing, and reopen the ventilators when the temperature begins to rise.

Ran up to 80° with air on fine days, and 5° higher after closing with sun heat, but do not overdo your Vines with atmospheric moisture until the colour in the leaves begins to improve. It is just possible the roots of the Vines may have gone down into the drainage or the borders may have become inert—two predisposing evils which cannot be grappled with until the autumn, when, as you suggest, they may be lifted and relaid in fresh compost. Meanwhile, give the Vines proper Muscat treatment. Mrs. Pince and Muscat Hamburg will not resent it, and, provided the Muscat is well rooted, you will soon find a great improvement in the new foliage.—W. COLEMAN.

LATE-KEEPING APPLES.

I CAN fully corroborate all that "A. D." says (p. 348) as to the excellent promise of a good crop of Apples of all kinds, and I heartily second his proposal that should we get anything like the promises of spring fulfilled in the autumn, that some means be taken to make the most of them by our home growers, by forming a company or some other means, so that the fruit is not crowded into the markets at gathering time, and the prices brought so low as to benefit nobody, and by the time the American consignments arrive there is really no stock of home-grown ones to oppose them. It is a singular thing that although even early or mid-season Apples are exhibited in good condition very late in the season, as described by Mr. Iggulden (p. 347), yet, as far as the market supply is concerned, our home growers appear to get cleared out very soon after Christmas. It is by no means an uncommon thing when a good Apple crop is general for the price to rule so low in the markets during August, September, and October as to hardly pay the growers for sending them any distance. Now, anyone used to Apple culture must be aware that it is to the soft Apples of the Keswick Codlin type that crop so freely, and which it is useless to try to keep any length of time, that the glut is due. The only thing to be done is to utilise them to the best advantage, and to reserve every kind that will keep, if only for a month, as even in the most abundant Apple seasons the home-grown supply soon fails from the very inadequate provision made for storing the crop. As for want of proper storehouses, the small growers send their crops direct to market from the tree, and once there they get into the hands of retailers, who, having even worse accommodation for storing than the growers, sell them at any price, so that Apples that would keep three or four months and be worth 50 per cent. more money are got rid of, to the injury of the home grower and to the direct encouragement of the foreigner. What we want is not only to grow more really good Apples that will keep until the spring, but, above all, to take more care of what we do grow, and it is to the wretched insecurity of tenants not only as to their land, but to any compensation for improvements, that proper storehouses for fruit are not one of the things attended to by them. A fine lofty building is not needed, as one half sunk in the soil will keep Apples far more crisp and juicy than one of the airy lofts that are frequently the only places for storing fruit, even in large gardens. As to laying Apples out in single layers, it is all very well for show fruit, but quite useless for market supply. I have proved over and over again that if stored in good sized heaps that the less they are moved about the better; in fact, like Potatoes, if sound when put together and stored in a dry place where the temperature does not fluctuate much, the losses will be far less if left alone than if turned over every fortnight. As companies are formed now for almost everything that offers a reasonable chance of yielding profit, I feel sure that if one were formed for buying up Apples that would keep, and storing them until the spring they would clear a large profit. JAMES GROOM.

Glasport.

SHORT NOTES.—FRUIT.

Fruit buds of Peach trees dropping.—Can any of your readers state the cause of my Peach trees dropping their fruit buds? They have been planted twelve months

last autumn and grew very well last summer; they are in a border 18 inches broad and 1 foot deep at the back of a lean-to vinery. When the buds should have begun to swell they all turned brown at the base and fell off.—A. M.

VINES AND GAS-TAR DRESSING.

A FEW years ago a mixture of gas-tar, lime, &c., was strongly recommended for dressing Vines and ridding them of bug and thrips, but I venture to say that it never has, and never will, come into general use. Many gardeners have been afraid to use it, and others, like myself, have not been satisfied with the results obtained. I will give my reasons for not using it, as they may act as a warning to others who contemplate its use. It is ineffectual, for it does not rid the Vines of these pests, and, in my opinion, no single annual dressing of any insecticide which may be used with safety can ever do so. My great objection to it, however, is that it is positively injurious to the Vines, for it so hurts the growing shoots that when an attempt is made to draw them to the wires, they snap off at the base so easily, that it is impossible to get them down safely, no matter how carefully the operation may be performed. During the first year I used the mixture I lost great numbers of fruiting laterals, many of which were showing the finest bunches; and I found at last that I must leave them untied, or lose all my crop of fruit; and, fortunately, I was able to leave them alone until the weight of the bunches brought them down. Though feeling sure that this was brought about by the tar-dressing, as it only occurred in the house where that was used, I thought I would try it again the following year, so I dressed alternate Vines in another house with the mixture, and got precisely similar results.

My opinion is that no insecticide will ever penetrate the crevices in the bark of a Vine sufficiently to kill all insects which are there, and dressings of such wretched compounds as the gas-tar mixture are worse than useless. With regard to the shoots snapping so easily after its use, I think the tar binds the bark round the bud and prevents its natural expansion, and causes the wood to become brittle instead of pliant; for I have noticed that the shoots on the Vines were smaller at the base than were shoots of a similar size from other Vines; while immediately above the base there appeared a warty excrescence which showed that something had injured them. I may be told that I allowed the buds to get too forward before using the tar, but I invariably prune early, and dress or clean the Vines at once.

Having had enough of it, I returned to my usual method of treatment, which is to scrub the Vines thoroughly with a strong solution of Gishurst compound dissolved in hot water, going over them twice with an interval of a fortnight. Besides scrubbing the Vines, I have the houses scrubbed and then syringed with water almost boiling, and then scrape off half-an-inch of the top surface of the border. This must be supplemented by strict attention and constant watching during the growing season. If the pest is bug, keep a bottle of paraffin in the house, and dip a small brush in it and touch the insects wherever they are seen on the wood; one drop will spread and destroy a colony. If thrips are the enemy, or if the bug has spread to the leaves, a sponge and some nicotine soap mixture will destroy them. Almost any insecticide will do if used carefully and frequently; all are useless without it. Make a point of looking over the Vines once or twice a week from the time they start until the fruit begins to colour. I cleared my houses from bug in two years by the above means, and was well repaid for the labour. C. T.

Grosse Mignonne Peach.—My experience with the above-named Peach has led me to quite the opposite conclusion to that given by "S. W." to "X." at page 318. I cannot think that "S. W." has had the true variety, or so good a fruit-grower and such a close observer as "S. W." is would have not condemned the variety in question so strongly. During the over twenty years I have been a head gardener I have never failed in producing good crops of it, and have come to look upon it as one of

the best cropping, most handsome looking, and finest flavoured Peaches grown. It certainly has the drawback of being difficult to pack when fully ripe. We have an old tree in our second Peach house that has never failed in producing a good crop for the past fifteen years, and I learnt from my predecessor here, Mr. Denning, that it had done well under his care for several years previous to my coming. I have picked traysful of fruit frequently that have weighed 7 oz. each on an average. If the border in which the tree is growing gets at all dry in the winter I find a tendency to bud-dropping just as the sap begins to move in spring. This year we have pulled hundreds of fruit off already, so thickly were they set.—H. J. C. *Grimston.*

GOOD APPLES.

TO THE EDITOR OF THE GARDEN.

SIR, I read your interesting paper THE GARDEN with much satisfaction and pleasure, and at page 347 I see a short notice of good keeping Apples, but it is a very scanty list. Having an excellent garden in the south of Scotland, I have taken a special interest in the question of having really good kinds and varieties of this most useful fruit, and I may say the following is a very good collection of fine fruit and most valuable in the house, some of them keeping in a good state until July last year. The following is the list of kinds produced:—

Gravenstein	Duchess of oldenburg
Alfriston	L. rd. Suffolk
Warner's King or Nelson's	Blenheim Orange
Glory	Bibston Pippin
Yorkshire Beauty	Beauty of Kent
Hawthornden, old and new	Lord Burghley
Rehlinville	King of the Pippins
Nather's Damppling	White Russet
Stirling Castle	

I have also young trees and grafts of—

Lane's Prince Albert	Early Julien
Lady Henniker	Cox's Orange Pippin
Lane's Incomparable	Braintree's Seedling
Golden Noble	Westwood Park Nonsuch
Rymer	Peasgood's Nonsuch
Cox's Pomona	Pearmain (two kinds)

besides some ten other kinds, names not known.

M.
** The above is a very good selection of Apples. There is plenty of early and mid-season varieties. The varieties we want are those that will remain fresh and crisp up till April and May.—Ed.

PROSPECTS OF FRUIT AND KITCHEN GARDENING.

SOME years ago, when looking at a fine lot of St. Michael's Pine-apples in a fruiterer's window in Manchester and noting the price of them, I said to myself, "Pine-growing in England is doomed." I afterwards ventured to say as much in one of the horticultural papers, and was taken to task for making reckless statements by others interested in Pine culture at home, and who dwelt on the superior quality of English Pine-apples and the desire to have these by those who knew what good Pines were, and so forth; but from that time till now Pine-growing has so rapidly decreased in private places, that it may be said to be now practically given up, while in the trade it has been given up entirely, I believe.

I refer to this subject now because it is impossible to ignore the fact that the same changes are likely to take place very soon in the case of not a few fruits and vegetables that have hitherto been grown in the home garden, which is fast being pushed to one side just as home farms have been, and which once supplied almost everything wanted about a gentleman's place, from the corn that made the bread, and the beef and mutton to the clothes that the people of the place wore. It is not so long since these changes in gardening began, and there are plenty of gardeners living yet who remember the time when, if a supply of fruits and vegetables failed at home, they could not be supplied from elsewhere, because the transport was wanting and the supply did not exist. It is different now, however. Look at the Apple and Pear supply, for example. Critics of our home fruit culture may talk as they choose,

but the fact remains that the American Apple supply sprung up after English Apple culture had been established for generations, and it has all but killed the home trade in good useful Apples, proving that other causes than our want of skill and energy have been at work to produce such a result. The wealthy now mainly buy select dessert foreign Apples and Pears, and prefer them to home grown, and no doubt they can be bought cheaper than they can be grown at home, all things considered, one reason being that when people buy, only what store is actually required is bought. At all events, you now find the American Apples by the ton in every village shop of any consequence, and the finer French Pears can be had either consigned direct or from the nearest town in an hour or two's notice. And it is the same with many other things. Look at early Potatoes, which it was once such a feat to produce a few mouthfuls of in pots and frames at or before Easter, but which you can now buy for a few pence. Broccoli and Cauliflower are the same. While the gardener in the north is sowing in August for a spring crop and carefully forwarding and tending them under hand-lights for six or eight months for the sake of a few heads, Cornwall Broccoli and Cauliflowers are being hauled about the country villages in hucksters' barrows at prices and of a quality the gardener cannot match. With most other early crops it is the same, and one naturally asks, is it worth while carrying on old and expensive cultural practices in private gardens, the reasons for which now do not exist?

I have never been able to regard a fruit or kitchen garden from any but a utilitarian point. In all cases the income should bear some reasonable proportion to the outlay, but the rule has been the other way. Private kitchen gardens have not, as a rule, been conducted on paying principles, or even on any pretensions to paying, or there would not be so many reductions now. The outlay on fruit culture under glass never, in many cases, bore any reasonable proportion to the possible returns. It is all very well and pleasing to some people to talk about the successful Grape culture, Peach culture, Apple culture, &c., of so-and-so and so-and-so, all of which have been chronicled often enough, but when did you ever see the cost of the extravagantly made borders, houses, and culture, &c., put against the result? I tell you the records of some famous gardens in these respects in bygone times would be regarded as simply scandalous by any committee of inquiry. In the education of our young gardeners in past times a good deal of blame lies at the door of their teachers, in whose works it is plain no considerations of this kind have exercised any influence. Of course, where proprietors have taken an interest in their own affairs, these things have not happened, and there are plenty of gardeners now who are alive to their duties in that respect.

Reverting to the fruit and kitchen gardens of private establishments, our opinion is that we shall see considerable revolutions before long, now that the private garden is looked at from a commercial standpoint much more than it used to be. The forcing of those vegetables and fruits that can now be had in the market cheaper and earlier, and often better, than at home will have to be given up. It does seem to me, as I have before hinted, a ridiculous thing to see good and practical gardeners forwarding for their employers at so much labour and expense early crops like Broccoli, Potatoes, Lettuces, &c., that are being sold for a trifle to cottagers at their doors, and it is the culture of these I would have discontinued and something better substituted, just as Pine-apples have been given up and been replaced by Melons, Strawberries, and other crops. I doubt, also, if the future will see so many extensive walled gardens formed, seeing those that exist do not pay anything like a fair interest on the original outlay, as regards the walls at least and the fruits from them; and as for shelter, it can be provided in a more ornamental and as effectual a form by means of trees and bushes. A much less extent of glass houses would more than provide the means hitherto supplied by brick walls, and be far better—the aim always being to grow such crops as are most appreciated and can be better supplied at home.

W.

SEASONABLE WORK AMONG FRUITS.

PINES.

THE earliest fruiterers, now well advanced, will require and will repay special attention; otherwise, the hard forcing to which they are generally subjected will result in disproportionate crowns if not in premature ripening. As days increase in length and the dry parching winds give way to more genial growing weather, the elongation of the crowns may be prevented by an additional supply of air. The syringe may be more freely plied, if not overhead, certainly over the surface of the bed and about the axils of the lower leaves, in which the stem-roots are now sufficiently advanced to be of great service to the fruit, and warm diluted liquid, soot, or guano water may be given to the roots whenever they require feeding. If all the Pines have not been properly supported, they should be well staked, as nothing looks worse than a lop-sided crown. All gills, as I have previously advised, must be detached and the suckers on each plant reduced to one, or at most two, which in private gardens will be found quite sufficient for future stock. The night temperature in this compartment may now range from 70° at night with a little air to 80° or 85° by day, also with air, and 90° to 95° after closing, with full sun-heat and moisture. As sun-heat declines, the fires must still be started in time to catch the night temperature at 75°, otherwise the admission of the usual chink at banking time will reduce the house too much before daylight, when early syringing will be delayed. Where blinds can be let down, or some other kind of covering applied, the rapid changes which take place through the early spring months can often be counteracted, and, be the materials ever so thin, the loss of heat and moisture by radiation in a great measure will be prevented. Moreover, fierce fire-heat, often so prejudicial, will be avoided and the fuel item considerably lessened. In these days of depression, it behoves all to look well into trifling details, and this matter of covering, not only of Pine pits, but houses of every kind in which a high and steady temperature must be maintained through long, cold nights, especially when the moon is exercising her influence, is worthy of the most careful consideration. These remarks are equally applicable to

Succession houses, in which the plants, consisting of Cayennes and Rothschilds as well as Queens, are now throwing up their fruit. Here the same attention must be devoted to top-dressing with lumps of turf, suckering, and staking, but the first two being comparatively shy sorts they do not often throw more suckers than are wanted for keeping up the supply of young plants. A steady bottom heat of 80° to 85° suits these plants well after the Pines are up, but it sometimes happens that sharp spring firing exhausts the moisture and the heat suddenly declines; when this is observed the plunging material should be levelled and well packed about the pots as a preliminary to the application of warm water, not to the roots, but to the tan or leaves. If this produces the desired effect, a slight covering of fresh material generally carries the plants through, and the objectionable practice of disturbing a plant after it has started is avoided. As these plants, especially the Cayennes and Rothschilds, will require more water than would have been good for the early Queens, the usual stimulants may be more freely administered, not haphazard at stated periods, but with a liberal hand when the plants actually require water. In the same way may water be passed through the syringe, not in drenching overhead showers, but about the walls, the paths, and every dry corner that will respond by throwing up a volume of warm vapour. Plants intended for starting later in the season must be kept well up to the glass, where they will make firm, stocky growth, and having the full benefit of solar heat, supplemented by liberal supplies of warm liquid, they will soon fill their pots with roots and check themselves into a fruiting condition. The temperature in this compartment may range 5° lower than in the preceding house, and should it be found necessary to shade, the texture of the material used should be of the lightest nature, otherwise the foliage will become

soft and elongated, and this even should only be applied for a few hours through the hottest part of exceptionally bright days.

Suckers.—In many places the potting of these was delayed by the inclement state of the weather, but all will now be making good progress, and the activity of the roots will justify daily syringing or dousing over and the moderate application of water. As few now grow large batches of Pines for market purposes, and private consumption is small, a few plants in every stage following each other step by step will best answer the gardener's purpose, as he will never be without plants in fruit or in a condition for throwing into that state. To carry out this method the first thing to be guarded against is superfluous stock, as to many it seems so strange to leave off at the twentieth plant where years ago the potting of one hundred would barely suffice. But then, on the other hand, the great half-yearly pottings, equal to two spring cleanings intensified, have now been broken up into half a dozen little goes, followed by the natural result, that we have just as many plants as we want and all are well treated. The foundation of these satisfactory little batches of plants no doubt is laid in the sucker pit or frame, for once a sucker becomes drawn no power can transform it into a broad-leaved, sturdy-fruited plant. Here, then, the grower must be ever on the watch; the bottom heat, sharp and sweet, must be kept about 90° for forming roots, 80° to 85° afterwards. The plants must be plunged near the glass, and room for full development must be made by constantly potting and moving a few of the best forward.

FIGS.

Early houses in which the fruit is now ripening, or approaching that stage, must be brought gradually round to a drier condition, not so much by the withholding of moisture as by giving more air, not by withholding water from the roots, but by giving them a thorough soaking and covering up the balls or beds with some dry, non-conducting material to check absorption in the atmosphere. Many people, on seeing the first ripening Fig, reduce fire-heat, suspend the syringe, and give more air; but all gardeners know the Fig is fickle enough without being made to undergo these indignities. Moreover, it is a dear lover of heat, and having, under our artificial treatment, two crops of fruit in two distinct stages upon it at one and the same time, we are obliged to temper our treatment to secure the shadow whilst guarding the substance. The ripening stage reached, my own treatment is as follows: The night temperature is allowed to range about 65°, with a little air at the apex, but no difference is made through the day, as advancing fruit must have a high temperature and a moderate supply of moisture, provided it is not stagnant and direct syringing is avoided. When the most forward Figs have been gathered, copious syringing early in the day and liberal supplies of warm liquid keep the second crop of fruit advancing, and spider during these give-and-take periods does not make much, if any, progress. If the second crop is heavy we thin off the least promising fruit, as this is the only safeguard against dropping. All spray is cut out, and gross shoots that have filled their allotted space, or are drawing too much upon the trees, are nipped and tied down to the trellis. Weaker growths, which form their terminal buds at the fifth or sixth leaf, are never pinched, as they produce the earliest fruit in the coming year. If it happens that root-pruning has been neglected and any of the trees develop a tendency to grossness, a general pinching, which induces fresh breaks, is the only means of checking and keeping them in order.

Succession houses.—Although the weather is unseasonably cold, the present month has given us a fair average of bright sun-heat, and, as a natural consequence, the fruit in these is swelling fast. If close pinching is practised, a few of the strongest growths should be checked every day, and tying down regulated in a way that future crowding will be avoided. When the fructifying stage is reached, patience, steady forcing with plenty of root and atmospheric moisture, combined with liberal thinning, will render this as safe as any other crop of

fruit, whilst neglect of these details, not forgetting the last, may result in the trees performing this operation for themselves.

Later houses having the benefit of artificial heat need not be hurried by daily firing, as they can be shut up with brisk sun-heat and moisture, and having the pipes to fall back upon, 50° to 56° can always be secured through the night. With us these trees are pushing heavy crops now about the size of Hazel Nuts, but they are grown strictly on the extension principle, the superfluous shoots being cut clear away in the autumn or whenever we feel disposed to throw them out of bearing for ripening up the wood. So long as these trees are kept growing they are never without fruit, and for this reason the amateur will find this not only the most simple, but certainly the most profitable mode of growing late summer Figs for his own use.

CHERRIES.

These in early houses having passed the stoning and thinning stages, a little more heat, principally from solar influence, may now be given. A low night temperature of 50° to 56° with a little air must, however, still be maintained, and with a liberal supply when the sun is shining full upon the house it may rise to 70° or 75° through the middle of the day. The step from stoning to colouring, especially of early varieties, is short, but it is quite long enough to enable the active little grub to decimate the crop. This, then, must still continue an object of attention, and so long as a rolled-up leaf or a perforated fruit can be seen, the depredator must be searched for and destroyed. The next and perhaps the only enemy is aphid—black, green, or brown, and as these soon tarnish what the weevils leave, gentle fumigating, whether they are present or absent, should always precede the colouring process. Fruit that is ripe or approaching that stage should not be fumigated; neither, if these precautions are observed, will it require it, as tobacco-smoke hangs about and destroys the flavour of otherwise delicious Cherries. When Cherries are ripe they will hang for a long time on clean, healthy trees, always provided the house is kept dry, cool, and well aired in fine weather. The most subtle enemy within is damp, but this can be prevented by the occasional and most gentle circulation in the hot-water pipes. The last and most ferocious destroyer is the blackbird, and he must be circumvented by small-meshed fishing nets dropped over the ventilators and doors.

PLUMS

carrying full crops of fruit must be kept thoroughly well mulched and liberally fed with diluted liquid; the syringe, too, may be plied twice a day, great care henceforth being observed in the choice of water that is free from lime or other sediment. If not already thinned, the superfluous fruit should now be removed with a pair of Grape scissors, leaving those intended for the crop as evenly placed as possible over the extremities of pyramids and bushes. All laterals and strong shoots must be kept closely pinched at the third or fourth leaf, more or less, in accordance with the size, or intended size, of the trees, a thin and evenly balanced growth combined with symmetry being the guiding points. Trees trained on trellises must also have their side growths closely pinched, to secure flower-producing spurs; but terminals, wherever space admits, may be allowed to extend, if not throughout the season, certainly so long as they do not interfere with the proper balance of the trees.

Insects.—Like the Cherry, the Plum is subject to grub, aphid, and spider, but the latter should not gain a foothold, neither will it where the syringe is properly used. Greenfly is easily destroyed by fumigation; black and brown aphid are most effectually dealt with by dipping the parts affected overnight in tobacco-water and thoroughly syringing the following morning. Soot water not very strong is an excellent wash and stimulant for use amongst all stone fruits, and a good supply should always be kept on hand. The easiest method of manufacture is as follows: Put a peck of soot in a bag, and sink it in the water-tank or in a cask, which should be kept regularly filled up, to ensure having the water perfectly clear and not too strong. W. C.

HORSE CHESTNUTS AT BUSBRIDGE,
SURREY.

THE noble group of Horse Chestnuts shown in the engraving is one of the many beautiful pictures of tree life that may be seen in the grounds of Busbridge Hall, near Godalming, the residence of Mr. Ellis D. Gosling. The trees stand on a natural mound of slight elevation, and on three sides are entirely unencumbered with wide stretches of level lawn running far away right and left, so that nothing hinders either a distant view of the whole group or a nearer observation of grand trunk and massive limb and delicate branch.

The sheltered and well-watered valley which forms the home portion of this beautiful estate is favourable to tree growth, notwithstanding its very poor sandy soil. Planes, Beeches, Scotch and Silver Firs are conspicuous from

and greenhouse plants, and even Ferns, apparently with no evil results whatever.—C. COLLINS.

FLOWER GARDEN.

DELPHINIUMS.

CALLING upon a friend in Staffordshire last summer, I was much struck with the beauty of a number of large bushes of Delphiniums growing in a border among the hardy flowers, in a choice collection of which he took great pride. It was worthy of notice that in a number of villa gardens near which my friend lives Delphiniums were conspicuous, and he told me they represented the overflow from his own garden, so much had his own seedlings been admired. And the matter of raising seedlings is a very simple one, for all that is necessary is to prepare a seed-bed in the open air, making it up with a nice free soil, drawing drills in it, and sowing the seeds without delay. The seeds should be placed in the drills as thinly as possible, some fine

rains and assists them in spring. Slugs are sometimes found destructive to the crowns, and they are more dangerous in the case of young plants than in well-established ones.

Among the new varieties recently offered are *Diomedes*, a semi-double variety, the outer petals of a beautiful soft azure blue, the centre clear mauve; *Excelsior*, an extra fine fully double variety, colour rich sapphire blue, the centre petals marbled with rosy mauve; *Falka*, single, Mexican blue and rosy mauve intermingled, good dwarf habit, and very free blooming; *Mrs. Barlow*, single, light azure blue and rose, prominent black centre, a beautiful and novel variety; *Mrs. Roper*, single, most pleasing pure pale cobalt blue and mauve, white centre; and *Thomas Tillbrook*, rich French blue, the base of the petals rosy mauve, a large double flower of great merit. It may be remarked that a good many new varieties are raised annually in Scotland, where the Delphinium is a great favourite.

I would advise anyone desirous of forming a collection to purchase a select number of good varie-

Horse Chestnuts in the gardens at Busbridge, Surrey. Engraved for THE GARDEN from a photograph by Miss Jekyll.

their great size and free development, and there are some Larches that are truly giants of their kind.

Narcissus Little Nell.—The Daffodil committee at their last meeting passed as a recognised variety a new one of Mr. Hartland's, called Little Nell. I think the committee were rather unwise to encourage the naming of insignificant and useless varieties such as Little Nell. I have always understood that one of the objects of the Daffodil committee was to name varieties which were an improvement on some other variety. I cannot make out what Little Nell is an improvement on. It seems to me to be inferior to *pallidus præcox*; indeed, I should not be surprised to find it is a small form of that variety.—D. W.

Sea sand for plants.—On p. 353 "S. W." inquires whether the sea sand recommended is procured from places covered by the tide or from the banks. Here it is procured from the beach, which is covered with water at the incoming of every tide, and is very salt; I have frequently tasted it. We use it here not only for cuttings, but ordinary stove

soil being put over them, and when the seedling plants are large enough they should be transplanted to a bed, carefully watered if necessary, and there they can remain until they flower. It might be possible, by sowing the seed in a gentle heat in February, to get some of them to bloom the same season; but probably it is more satisfactory on the whole to sow in the open ground, and allow the plants to grow on into size according to their own natural robustness. As the flower-stalks of the Delphinium are liable to be snapped off by the wind, stakes should be placed against them; in the case of young plants, one will suffice, but when a plant puts up several shoots, three at least will be necessary. Unless seed is wanted, it is best to cut away the flowering stems directly they have gone out of bloom, as growth in the form of side shoots is encouraged, and later flowering stems arise. Strong plants will last for years in the open borders; they make an excellent back row with Dahlias, and they are greatly helped if some mulching be given to them in the autumn in the shape of manure, which is carried down to the roots by the autumn

ties and save some seed from them, and raise seedlings for themselves. A few really good and distinct sorts from which something fine could certainly be raised are *alopeuroides*, rich blue; *Belladonna*, pale blue; *Brilliant*, rich deep blue; *Eclipse*, brilliant blue, extra fine; *George Taylor*, rose, laced with pale silvery blue; *Madame H. Jacotot*, bright sky blue; *Pompon Brilliant*, bright indigo blue; *Madame E. Gant*, deep blue, shaded with purple; *Sultan*, almost white; and *William Pfitzer*, brilliant sky blue, large, and fully double. The foregoing is a select list, and I am certain none of them will disappoint. R. D.

Double Primroses.—I am much interested by Mr. Wm. Elliott's note in THE GARDEN, April 9 (p. 336) on double Primroses. Can Mr. Elliott give any further particulars of the origin and history of these flowers? Does he attribute the double *Polyanthus* to *P. altaica* also? I do not know this *Primula*, but I find the date of its introduction to our gardens is 1819, and if that be accurate, it brings double Primroses much more within the range of

modern history than tradition would lead us to suppose. The only double Primrose that flowers all through the winter with me is the double white; whereas I find single ones of various shades produce flowers from time to time from the beginning of December onwards. It would be interesting to know the history of the new double yellow Primrose also, and how it escaped any taint of the altaica in its ancestry.—*SCOLEPENDRIUM*.

New varieties of Primula Sieboldi.—Mons. Victor Lemoine, of Nancy, to whom English horticulturists are indebted for so many good things, this season announces three new forms of *Primula Sieboldi*, viz., *Alba Magna*, with large, pure white flowers, stout, bold, and of the finest quality; *Diane*, rosy plum, extra fine; and *La Ligne*, rosy purple or violet, with a distinct white eye. The former should be a good addition to our collections. Good whites are requisite in order to provide a proper balance to flowers of deep and striking colours.—R. D.

Eulalia japonica variegata.—As a "dot" plant this *Eulalia* is a capital subject in the flower garden during the summer. Small plants with at most three stems at planting time are best suited for this purpose. As a carpet, *Mesembryanthemum cordifolium variegatum*, *Herniaria glabra*, or any of the dark or bright-leaved varieties of *Alternanthera* answer well. Now is a good time to divide any plants which have been used last year for bedding or which have been grown in pots. These should be potted in sandy and not over-rich soil and placed in a cool temperature, and they will quickly grow into useful plants.—E. M.

Mule Pinks.—These are most useful plants in the flower garden, and of late years they have come to the fore, especially the rich-coloured varieties of which Napoleon the Third is such a conspicuous type. Some are single and some are double; they are, as a rule, free growers and bloomers, and appear to do well in a soil that will suit the garden Pink. They can be readily propagated by means of cuttings which are made from the young growths which spring from the base of the flower-stalks. Such varieties as can be had will be found in the following list: *Abbotsfordianus*, light rosy purple, large flowers, a strong grower; *Atkinsoni*, single, intense vivid crimson, very showy; *hybridus multiflorus*, deep rose, very free; *Marie Paré*, pure white, a free grower; *Lady Campbell*, pale pink, dwarf, good; *Little Gem*, white; *rosens floribundus*, bright rose, very free and pleasing; and *speciosus flore-pleno*, reddish purple.—R. D.

Claytonia virginica.—By planting this much-neglected subject, all sorts of out-of-the-way and unsightly places, bare patches under densely shading trees, exposed mounds in woods, &c., may be rendered beautiful during the spring months. With us it has grown equally well in shade and in full sun, and in damp as well as dry situations, requiring little or no attention when once fairly established. In some districts of England it is said to grow wild, and its scarcity is the less easily understood, seeing how greedily the birds feed upon the seeds. It is quite distinct from *C. perfoliata* by the separation of the upper leaves at their base, besides their being of a bright, shiny green colour and quite succulent. The seeds, when shed in the latter part of summer, germinate freely in the open air, and no fear need be entertained of the crop failing unless under exceptionally severe weather; the flowers are white, varying to pink and rose. It is common all over North-western America.—K.

Two good spring-flowering plants. Of all my recollections of the matchless spring gardens at Belvoir Castle, Grantham, nothing seems so impressed on my memory as the effectiveness of the large patches of *Myosotis dissitiflora* and *Omphalodes verna* which Mr. Ingram uses so largely and with such happy results. I never before, and I have never since, seen the beautiful creeping *Forget-me-not* (*Omphalodes verna*) so much at home as at Belvoir. On the slopes, just within the shade of trees, it grows into dense masses and flowers profusely, and with such a glorious hue of clear blue! Moisture and shade suit it. I once saw some very pretty patches in an old farmhouse garden in Kent

on a rather stiff, clayey loam, but doing finely on a north aspect, untouched from year to year, and apparently reveling in a freedom properly their due. I have a patch of it under an east wall, and just where the shade from a bush Pear tree falls upon it; it is now coming into flower nicely. Of *Myosotis dissitiflora* one cannot speak too highly, and in the rich soil on the slopes of Belvoir it grows and blooms with wonderful vigour and freedom. Unfortunately, it is not nearly so hardy as *Omphalodes verna*, and it suffers greatly in such a winter as that we have just passed through. I had a very fine plant of it growing in a large pot that in December last was a marvel of size and robustness, but, though placed in a cold frame, it was completely killed. Out of doors, large numbers of it have been killed, in common with Stocks, Wallflowers, Antirrhinums, &c. If it was only as hardy and persistent as the common blue *Forget-me-not*, its value would be increased tenfold. But it will always be a precarious subject to carry successfully through our English winters, unless occupying a favourable position in the open air.—R. D.

THE FROST AMONG THE SPRING FLOWERS.

THE winter of 1886-87 will long be remembered for its heavy snow-storms and long continuance of cold weather. No frosts of exceptional severity occurred. In no part of Great Britain, so far as I am aware, did the thermometer run down to zero, though on three different occasions it fell to within 4° to 6° of the same. But the length of the frost seems to have made up for its lack of extreme severity, and seldom have Wallflowers, Violets, *Forget-me-nots*, and even Primroses been more severely hit than this season. Hardy vegetables, such as Cabbages, Lettuces, Broccoli, and even Flanders Spinach and Parsley, have also well-nigh disappeared. We imagined that all these flowers and plants were simply resting safely under a foot or more of snow, but instead of that the majority of them were perishing. Hence, when the snow finally left us, borders of Violets and *Forget-me-nots* and other plants looked as if they had been parboiled. The leaves were as black as one's hat, or completely rotted off, and the slaughter of the innocent Violets in embryo of thousands and tens of thousands of the *Marie Louise*, *Comte de Brazza*, *Queen Victoria*, and *Czar* was enough to make all lovers of spring flowers weep. But the most complete wreck of all were our borders and blocks of the lovely *Myosotis dissitiflora*. Of late years we have mostly left it in its winter quarters till the spring, moving the plants into their blooming beds and borders in February, March, or April, according to the weather and other circumstances. This year we have scarcely a plant left alive for blooming. I have never seen such a slaughter before. It is not simply the loss of the earlier blooms—that is no uncommon experience—but the whole plant, root-stock and all are killed. All this destruction or most of it happened under the snow, which we have mostly found to be a coverlet of safety.

The cold-resisting power of Violets in the open I have found to run in this order, beginning at the least and rising with the increase of numbers into the greatest: No. 1, *Comte de Brazza*; 2, *Marie Louise*; 3, *Neapolitan*; 4, *Victoria Regina*; 5, *Czar*; 6, the old double and single Russian varieties. On the first two, most of the earlier flowers as well as the finer leaves are destroyed; on No. 3 the flowers have mostly escaped, though the leaves have been severely pinched; on the next two the big leaves are destroyed and the earliest blooms, but many of the smaller ones are intact; the two Russian varieties have suffered least of all.

A rather striking case of the effects of culture on tenderness occurred in the case of some *Neapolitan* Violets. These were planted on a poor border, and made but scant growth, and the small leaves and embryo flowers are intact and uninjured on the starvelings; while the well-fed plants, with fine heads of foliage and embryo bloom, are completely wrecked. One more lesson the frosts of this winter have taught, and that is, to hasten back to the good old rule of transplanting spring flowers late in the autumn. If not convenient to mass them in their

flowering quarters at that season, hitch them over where they stand, or on to fresh storing ground towards the end of October; and thus, by checking growth and reducing the percentage of watery sap, multiply their chances many times of passing safely through the most severe winters. This double transplanting causes extra labour, but old-fashioned experience and the comparative safety of many thousands of such a sensitive test plant as *Myosotis dissitiflora* for many years prove that double moving is far safer than once, and that autumnal planting is the best means of ensuring the safety of this superlatively beautiful spring plant. D. T. F.

Chionodoxa Luciliæ.—Mr. Brockbank does good service in calling attention to the *Chionodoxas*; they are charming spring flowers. Four years ago I planted some *C. Luciliæ*. The first year they flowered very weakly, and the blooms were small, few on a truss, and generally rather disappointing. But since then they have gone ahead, until now they are splendid. Some of the blooms are very large, the centres pure white, shading off at the tips to a brilliant nemophila-blue. The truss stands fairly well up and bears several blooms. I find also that seedlings have come up near to them and have flowered nicely for young bulbs. *Chionodoxas* are not nearly so much grown as they deserve to be.—ANTHUS.

The Daffodil committee and naming of Daffodils.—With reference to what has been said on this subject by Mr. Scrase-Dickins, had I known, as I do since I came to London, that the naming of Daffodils was to be so restricted in future, I do not think I should have at all sent up yellow varieties for consideration, and I believe from what fell from the chairman at our last meeting, there was a resolution to some such effect passed at the end of the session last year. But in the case of white Daffodils the best thing for me to do now is to lock them up for future observation, though I think I convinced our respected hon. sec. that he had a hidden treasure at Coolhurst, which was only known to him as common cernuus, and also at some of the local Daffodil grounds I saw this Austrian giant towering above the common type of ordinary cernuus, so that soil did not in the least change its nature at Coolhurst or Tottenham. I would suggest in future that all the workings and sayings at our Daffodil committee meetings be taken down by a shorthand writer, and kept in a sort of blue-book for the good of future generations. It is an old saying, "the word dies, but the letter remains," and at the end of the session the year's work could be published in pamphlet form and distributed to members for their guidance. For instance, if a new seedling of advanced proportions be raised and named, it may be ten years before such could be distributed, members then having their book of reference would easily be educated as to its value. I shall be most happy to subscribe towards the work of both the shorthand writer's assistance and the publication of reports.—W. B. HARTLAND.

P.S.—I am very sorry we have not the full report in pamphlet form from the start in 1884.

Doubling of hardy Primroses.—I expressed the other day a belief that *Primula auriculaeflora*, so-called, was the single progenitor of the old double crimson Primrose. That all doubles have originated from singles in that way there can be no doubt, and I am satisfied of the fact for two reasons: first, that very often doubles have thrown single flowers, and, second, that very often singles will show a tendency to produce superlative petals, the anthers becoming petaloid. I have, for instance, noted that tendency in a number of flowers this spring, and think it probable that were the indication specially followed up, that some really double forms might further be developed. I am not a great admirer of double Primroses. They produce no seed, and cannot thus easily be increased, and they have no eye, which seems to be the peculiar charm of all the singles. I have seen cases in which both the double white and lilac have reverted to singles, very pretty forms, but which, like so many more dependent upon division, soon died away. Then it is noteworthy that all doubles

in reverting show thrum-eyed forms. That seems conclusive proof that authors change into petals only when prominent, as in thrum-eyed flowers. All the forms which I have observed showing a doubling tendency are thrum-eyed. That we get so few new doubles in hardy Primroses is possibly due to the wonderful increase in new things in the way of flowering plants which has taken place during the past half century, and now florists have little time, and perhaps a little inclination, to turn to the doubling of hardy Primroses. I have not heard of any instance in which any member of the Primula family has, in a wild state, been found with even semi-double flowers, not even a wood Primrose; hence it would seem conclusive that doubling is a product solely of cultivation aided by selection. A. D.

GLADIOLI.

TREATMENT OF THE SPAWN.—The spawn, as it is familiarly called, means really the small bulbules, or bulblets, which cluster round the bulb in more or less profusion, and which afford a curious illustration of variety in the production of the same results, for these small bulbules are of various sizes, shapes, and position. The most ordinary sort is that shaped like an egg, but with a sharp point at either end; this consists of a hard outer shell, and of a soft inner body which is easily damaged; when planted this outer skin decays, and the inner portion starts the shoot at one extremity, and the roots at the other. These bulbules cluster round the base of the newly-formed crown, between it and the old decaying one of the previous year, but in some cases they are formed at the end of a leafy stem about half an inch long, and several of these are clustered together. When a bulb is taken up it will be found that many of the bulbules are not fully ripened, and that the outer skin is not formed. Then there is another form in which the spawn is found, viz., in a very hard boat-shaped case; this fits on its concave side to the corn, and is sometimes found outside its outer skin, but also frequently within it. When this case is opened it is found to contain a bulbule, and sometimes two, or even three. I have opened one this morning (April 16) containing three.

Then, again, it is remarkable how varieties differ as to the number of bulbules they produce. Adolphe Brongniart and Mme. Desportes rarely have any, while Horace Vernet and Baroness Burdett Coutts produce them abundantly, and this to some extent accounts for the fact that some varieties are ten times the price of others which were "let out" in the same year, so that amateurs must not imagine that of necessity they will be able to reproduce the varieties at will.

It is, I think, a question for an amateur who grows on a small scale whether it is worth his while to trouble about the spawn, unless of new and scarce varieties. In former days, when the corns were much dearer than they are at present, it was a different matter, but now they are so cheap, that when a good-sized bulb of many exhibition varieties can be had for 3d. or 4d., it is hardly needful to wait for three years, which is about the time that it takes to produce good flowering corns, and to have all the trouble for so little result. My advice would be not to attempt it unless in the case of such varieties as I have indicated, new or scarce ones.

But if an amateur is determined on growing Gladioli from spawn, in what way is he to proceed? There are two methods which have been adopted, one which I have seen at Fontainebleau, and with Mr. Dolere, of Wellington, and I believe with Mr. Kelway, of Langport, viz., culture in the open air. A piece of ground is chosen on an open and well-drained spot; drills are then drawn about 1 inch apart and about 2 inches deep; a little sand is placed on the bottom of each drill, and the small bulbules are then carefully planted about half an inch apart; the drills are covered in the ground levelled, and should the weather be dry the ground should be watered. When the bulbules appear, which they will do in about a month or six weeks' time, they appear like blades of Grass, and being

slender must be kept clear of weeds, which are apt to smother them. When the weeds appear in the drills amongst the young shoots great care is needed, lest in pulling up the weeds the small bulbules are dragged up with them. They should be watered if the weather be dry, and after each watering the hoe should be gently drawn across the ground between the drills so as to prevent it from cracking and becoming unkindly.

There is, however, I think, no doubt that time is gained by growing them on bottom-heat. Where the space can be devoted to them, a small frame will be the best place for them; a little gentle bottom-heat may be given to them, and they will come up of course more quickly than in the open; indeed, I think quite a year is gained by this process. Where, however, it is desirable only to propagate a few in this manner, it will be better to sow (if one may use such an expression where seed is not the subject treated of) them in pots, and then plunge the pots in a bed, or else place them on the surface in a Cucumber or Melon frame. When they have come up and grown about 6 inches in height they may be either plunged as they are in the open ground, having first been hardened off in a cold frame, or else turned out, keeping the ball of earth entire, and then taken up in the autumn before the crop of old bulbules is lifted. They should be kept in dry sand during winter, as the bulbules being small they are more apt to shrivel up.

I have mentioned that many of the bulbules have a very hard skin. Many years ago when my friend Mr. Banks, of Shelden Lodge, near Deal, used to grow Gladioli largely (and from whom I have received many a wrinkle in their culture) he used to tell me to adopt the plan of breaking the outer skin so as to give the infant corns a better chance of growing; there is no necessity for removing it altogether, but care must be taken not to injure the small bulb itself, as a bruise brings on decay and death. But when this outer skin is judiciously removed it gives them a much better chance of growing; indeed, I question whether those enclosed in the boat-like cases to which I have alluded would ever germinate if it were not done. DELTA.

Double Violet Victoria. The origin of this fine double purple Violet, which was shown by Mr. Chambers, of Isleworth, at the last meeting of the Royal Horticultural Society, and awarded a first-class certificate of merit, is decidedly interesting. Mr. Chambers states that it is a chance seedling, and came up in the open ground close by beds of the Czar and the Neapolitan, and the assumption is that it is the result of a cross between the two, effected in some way, probably by insects. Several seedlings came up, but this was the only one with double flowers, and an excellent find it has proved. It appears to possess a good deal of the habit of the Neapolitan; it is wonderfully free, and promises to make an excellent variety for pot culture.—R. D.

Honesty (Lunaria biennis).—The hardy biennial Lunaria is well worthy of culture, if only for its excellent effects as a green foliage plant in the winter and spring. Where grown, as a rule, it is too much the habit to treat it as the spotted Fox-glove is treated, that is, as a weed, tolerated but not cultivated. The seed is allowed to drop about and grow as it can. Thus, for lack of culture, the successive seasons' products become weaker, and eventually die out. Then these biennials are regarded as rubbish, and get no further attention. If we treated all our garden flowers in the same way, how many of them would come to grief. Now Honesty dislikes being transplanted, unless it can be lifted in the autumn with balls of soil. The roots are somewhat fleshy and strike deep. The best plan, therefore, is to sow seed in small patches here and there where the leafage will tell with good effect in winter, and the spikes or heads of flowers in the spring. Seed should be sown not later than April—indeed now is the time to do so—just marking the patches here and there with a piece of stick until the seed has grown, and that will soon be. Single plants will form big clusters of leafage, which, being green all the winter, are very helpful in

keeping spaces in shrubberies, or herbaceous plant borders somewhat cheerful. The dark purple and the pure white kinds are the best. An old form, somewhat taller, has pale purple flowers; not a few of the dark purple flowers will often come flaked and variegated, but self-hues are the most effective. The seed-pods and stems allowed to dry and carefully preserved are, when cleaned carefully of the seed, very pretty and most helpful in winter decorations with dried Grasses and flowers. Thus the Honesty serves several useful purposes. A. D.

Crowded bulbules.—Bulbules generally get too thick in the ground if they are left undisturbed for a few years, and as a consequence the flower-stems are weaker and the individual blossoms small. This is especially the case with Tulips, Grape Hyacinths, and strong-growing Daffodils. When the bulb borders are periodically gone over and such as are too thick taken up and divided, overcrowding does not occur. Now is a good time to go through the borders and mark such as require to be thinned out, and then they can be attended to in the autumn.—J. C. C.

Papaver nudicaule. Who can help admiring patches of these pretty Iceland Poppies when they are in flower. Natives of Siberia and the northern parts of America, they possess a hardihood that fits them for English gardens. There are several varieties, but the three most distinct and most worthy of attention are the ordinary type, with bright yellow flowers; *P. nudicaule album*, pure white; and a fine variety named *P. nudicaule miniatum*, with intense orange-scarlet blossoms. This last was awarded a first-class certificate of merit by the floral committee of the Royal Horticultural Society last year. These Poppies can be grown in beds or borders, or planted in the rockwork, for they appear to be lovers of moisture, or they may be planted in clumps with other hardy things, when they will prove very attractive, being of a neat and graceful habit, and having bright green Fern-like foliage, produced in tufts. These characteristics, combined with perfect hardiness and profusion of bloom, place them in the front rank of hardy flowers. It is not too late to sow seed, nor is it difficult to procure it. It can be sown in light sandy soil, and the seedlings raised in a cold frame.—R. D.

Trientalis europæa.—A charming little plant native of various parts of Britain as well as other alpine countries of Europe, and extending even to America, where the forms *arctica* and *latifolia* are found. There is an allied species called *americana* in cultivation in our gardens. When botanising on the bleak moors of Ross-shire last summer, I met with large tracts of land white with this pretty star-like flower, shown off to advantage against the whorl of five or six narrow, acute leaves. It was growing in bleak and exposed places, as well as in moist, shady woods. In the latter situations, however, it was most abundant, and owing to its increased robustness was able to raise itself above the surrounding herbage. Although not exclusively confined to Pine woods, it was more prevalent in such places, and seemed to thrive and increase much quicker than when fully exposed. As seen in its native wilds, I know of nothing to surpass the quiet beauty of this lovely little alpine, it harmonises so well with the surroundings. There is no reason why this little starry gem should not be a common inmate of our gardens, as it could be very well accommodated in the vicinity of Pine trees, where Grass grows but sparingly, and Ivy is a little too robust; shady nooks in the rockery where its roots can run at will, and where it would not be crowded, would suit it admirably. When taken up with a bit of turf there is no doubt of its growing, the piece we brought being now fully established and thriving nicely.—K.

Auriculas, &c.—It is worthy of remark that whilst the southern exhibition of the National Auricula Society will be held on Tuesday next, yet here of several hundreds of hardy Auriculas in the open ground not a plant shows a single flower, and it is improbable that there will be any considerable head of bloom under a month. In such a case the holding of a show of this hardy plant next week

seems rather out of season. Of course, only pot plants, and most of these probably pushed on in heat, will be staged. If such is the state of things here in the south, further north the plants must be much later. I have never found outdoor Auriculas to be so late as this year. Then gold-faced Polyanthus, always later than the fancy or coloured ones, are so behind outdoors also, that very few flowers are expanded; whilst the fancy section, though more forward, has been greatly hindered by drought and very cold nights. Thus it will seem very incongruous that an exhibition of certain hardy spring flowers should be taking place long before similar plants in the open air will be in bloom. It is rather odd that whilst even in unheated houses during the day the recent brilliant sunshine has proved to some growers rather troublesome, outdoors it seems only to have served to bake the soil and bring out into striking contrast the exceedingly low temperature, with sharp frosts at night. Even the hardiest of plants may well feel unsettled when the temperature ranges from 26° at 4 a.m. to 60° at midday; and of the contending forces of cold and heat, the demon frost seems so far to have got the best of it.—A. D.

Cactus forms of the Dahlia.—Whether they are grown for cut flowers or as decorative subjects in the garden, the Cactus forms and a few others are, in my opinion, of much more value than the great bulk of the single ones or those of the show class. In a cut state the Cactus forms are very beautiful, and they are no mean ornaments in beds or borders. The best white-flowered variety is Constance, which grows freely and produces a continuous supply of flowers until quite late in the autumn. Mrs. Tait is another white variety of considerable merit; there is a peculiar appearance in its serrated petals which makes it rather attractive. When better known I think it will be esteemed as much as the preceding. Mrs. Hawkins is also a very beautiful flower late in the autumn, as then the rich sulphur colour is very pleasing, while under a strong sun the colour is much lighter. Juarez is the well-known scarlet form, and taken altogether it is as useful as any. The informal build of the flower is as striking as its bright crimson colour; without this sort to associate with the others they would be comparatively unattractive. It is a vigorous growing kind, and the blossoms are produced freely. Cochineal is very similar in colour to the last named, but a useful variety nevertheless. Glare of the Garden is very effective either grown in a mass or as single plants; for an isolated bed on a large lawn (as I saw it at Powderham Castle) I have never seen another tender plant so effective, for the whole bed was one blaze of colour. The growth is dense; the flowers, rather small, are as brilliant as those of a zonal Pelargonium. No list of Dahlias grown for cut flowers would be of much value if it did not include the single variety named Paragon. *Picta formosissima* is an attractive flower when it can be secured in its right form. The bright red stripes on the yellow ground are very telling, but it cannot always be depended upon to produce blooms possessing this character.—J. C. C.

SHORT NOTES.—FLOWER.

Plants for bees.—Will any of your readers kindly give the names of say twelve or twenty four of the best varieties of plants suitable for bees, and of which seed may be obtained?—J. SMITH.

Campanula muralis alba—Anyone requiring a suitable plant to cover the stones which are used in some gardens as edgings instead of Box could not do better than plant this Campanula. It flowers very freely during the summer months, and is easily increased by division of the roots in the spring.—E. M.

Viola canina alba.—My son had the good fortune to discover, last week, a plant of this variety. The flowers are of the purest China white, stem leafy, leaves heart-shaped and acute, sepals acute. As far as I know, *V. canina alba* is not in commerce, and I am inclined to think that I may be the fortunate possessor of the only specimen of the species in existence. I shall be greatly obliged if readers of THE GARDEN will kindly enlighten me on this point.—H. A. W., *Boughton Malherbe*.

Primula ciliata purpurea—This variety is now in full flower with me. It is a gem among the hardy Primulas, and is remarkable for the freedom with which it blooms and the rich, dark magenta-purple flowers. A variety named

coccinea is an excellent companion to it; it is of a bright reddish-rose colour. I have several strong plants in pots of *P. marginata*, not one of which has flowered this season. They are in the highest degree vigorous, but they give me no bloom. Can anyone explain the cause of their not flowering? The plants have been all the autumn and winter in a cool house with Auriculas.—R. D.

THE WALLFLOWER.

PLANTATIONS of these put out in the open ground at the end of the summer have suffered greatly in some positions more than others. I think that the winters have been much more trying to hardy plants of late years than any we have had for some time, and losses are only just beginning to make themselves apparent. But that the Wallflower should be so much injured is a serious matter, for is it not one of the most popular of spring flowers? and bunches of their fragrant flowers scent the air when they are in season.

That the Wallflower is closely related to the Stock there can be no doubt. There is a section of Stocks, termed Wallflower-leaved, in which the foliage appears to very closely resemble that of the Wallflower. It is said that we owe the Wallflower to Spain, and that it came to us originally under the name of Wall Stock Gillflower, which afterwards became Wall Gillflower, and finally Wallflower.

Of the common Wallflower there are several varieties, and they are all so serviceable as to deserve a place in the garden. Wallflowers are grown very largely for bunching for market, and the favourite Covent Garden strain is one with a very free-branching, dwarf, compact habit, and producing fine trusses of dark chestnut-crimson flowers, which are stout and of fine shape. There are choice strains of dark Wallflowers with larger, but looser flowers, but they are scarcely so pleasing to the eye as a good strain of the Covent Garden type. The tendency of this Wallflower is to commence to bloom in October when the autumn is mild and fine; hence, there is a selection called Harbinger, but it is much more a question of weather than anything else. The finest strain of large-flowered yellow Wallflower is the Bedford Giant Yellow, an exceedingly fine garden variety, with large, stout, well formed, golden yellow flowers. This is a selection from Carter's Tom Thumb, which is somewhat of a misnomer, because it is of tall rather than dwarf growth, but yet a very useful variety. The true Tom Thumb Wallflower is that which we know as Belvoir Castle Dwarf, or Ware's Tom Thumb or Dwarf Pigmy, a very dwarf, free-branching, pure yellow-flowered type that is most useful in the spring flower garden. I think the credit of having fixed this strain belongs to Mr. W. Ingram, of Belvoir Castle, who has used it with great effect for many years in his unrivalled spring garden at Belvoir Castle. The seeds of the last-named are small and of a yellow colour; the seeds of Bedford Giant Yellow and Carter's Tom Thumb are quite dark.

Among the single German Wallflowers may be found pretty shades of violet and purple. Efforts have been made to fix these, but without much success. Seed saved from them will produce variously-coloured flowers. Last spring, when visiting Mr. Samuel Barlow at Llandudno, I found he had two or three very fine types of purple single Wallflowers, but he very wisely propagated them by means of cuttings so as to have a good stock of them. It is probably only in this way that anyone can be sure of perpetuating these colours. Many people sow their Wallflower seed too late in the summer to ensure getting good plants in flower in spring. It may be said that large, well-established plants suffer more from the weather than those in the seed beds, and doubtless this is true; but it is exceptional to have a large quantity of plants destroyed. The weaker plants may remain in the seed bed, and if they stand better than the old ones they will come in useful to supply gaps caused by the rigour of the winter. If they can be lifted with balls of soil attached to the roots they will not suffer by the removal, but soon establish themselves and do good service in their own time.

R. D.

Harrison's Musk for bedding.—Apart from its delightful fragrance, this Musk is a very useful plant for many purposes. When grown in pots it is as suitable for the window as for the greenhouse or conservatory, as in a fairly light position and with plenty of air and root moisture it will remain in bloom for some time. It is also very pretty when grown in a suspended basket, if care is taken to have the sides furnished with plants low down as well as at the top. This is not difficult if the basket is well lined with Moss, and the young plants have their roots bedded in the soil and the tops brought through so that as they grow they may hang down, but it is as a summer bedding plant that I value it most. Where there are a number of small beds to fill, this Musk is not only sufficiently attractive to be pleasing, but the odour given off by the flowers is very powerful. It is a plant that requires a good supply of water when in active growth, whether grown under glass or not, and to be successful with it as a bedding plant it requires to be regularly watered in dry weather. I may remark that it is a very suitable plant for the summer as an edging to beds of moderate size.—J. C. C.

PROPAGATING.

FICUS.—The species of Ficus in the propagation of which the greatest interest is centred is the India-rubber plant (*F. elastica*), for it is a general favourite, and many are the inquiries made as to the best means of propagating it. This Ficus is by no means a difficult subject to strike from cuttings—that is, if the cuttings are in a suitable condition—but it is useless to take them from a plant that is at all stunted or unhealthy, and at the same time a fair amount of heat is necessary. Where required in quantity a few large plants should be kept to supply the cuttings, and they may be stood thickly together in any out-of-the-way part of the stove. Such plants will be by now completely studded with young shoots, every one of which may be taken off and inserted as a cutting. The weaker shoots strike root far more readily than the strong ones, but shoots taken from old stock plants, even if stout and vigorous, root with more freedom than those from the young fed-up specimens such as are usually offered for sale. In all propagating matters it should be borne in mind that cuttings taken from plants that have been fed up with stimulating manures can seldom be relied upon to strike in a satisfactory manner. From 4 inches to 6 inches is a very good length for the cuttings, and, having been cut off cleanly just below a joint, they are then ready for insertion. One way to do this is simply to stick the cuttings in the Cocoa-nut refuse which usually forms the plunging material in the stove, and cover with a close propagating case. This method certainly economises space, and, given a gentle bottom-heat, the cuttings soon strike; but the roots produced in the Cocoa-nut refuse are very fragile, and great care must be taken in potting them. Perhaps the more satisfactory way is to put each cutting singly in a small pot, as so treated any particular one can be at once withdrawn and the others left undisturbed. The soil for the purpose should be moderately fine and of a light sandy nature; while a few broken crocks and pieces of charcoal mixed with it assist in the formation of roots. The cuttings should be put in firmly and fairly deep. A good plan is to put a crock or two in the bottom of a 24-inch pot, then in the case of a large cutting the base of it will rest upon the crocks, and a few broken small may be put in before the soil is added thereto. As this drainage material clusters around the base of the cutting it is a great advantage. When the cuttings are put in each should be tied securely to a small stick, as being so heavy they are liable to become loose, and thus retard the action of rooting. After a thorough watering the pots must be plunged in a bottom-heat of about 80° and kept in a close case. They will need less air than the cuttings of many other foliage plants, as this Ficus seldom decays, even if kept close for a long time. Besides cuttings of the entire shoots, this Ficus can be increased from single eyes,

each with a leaf attached, and the best time to do this is just as the bud at the base of the leaf is very prominent and ready to start into growth. To bring about this result when any long vigorous shoots are to be propagated from, the better way is to take off the top just far enough for the cutting, and allow the remainder of the shoot to remain on till the buds at the top part are almost bursting into growth, when they may be cut up into single eyes and each one of them put in as a cutting. The piece of naked wood below the leaf will serve to hold it secure, and as an additional precaution each leaf should be secured to a small stick. Besides these methods of increasing the stock of *Ficus-elasticus*, I have treated it with most satisfactory results in the following way, which seems very little known, viz., to graft the shoots on pieces of their own roots, which soon unite and grow away without check. Wherever there are large plants, roots of this character are by no means difficult to obtain, and the grafting operation is very simple. The root should, if possible, have a few attendant fibres, and the graft should be inserted in the upper part by simply splitting the stock, and having fashioned the base of the shoot in the form of a wedge, it must be inserted in its place and tied securely in position. The grafted plants must then be potted in such a way that the point of union is below the surface of the soil, and this being done, they should be placed in a close case and treated as cuttings till growth commences. With regard to the other species of this genus, some of them, such as *radicans*, *repens*, and others, will push forth roots from all parts of the stem when they are in a moist atmosphere or come in immediate contact with any damp substance. Again, others that include among their number *Parelli*, *excultus*, and *macrophylla* strike root if taken as ordinary cuttings, and inserted in the usual way. Should the least sign of thrips be visible on the cuttings, the leaves must be carefully sponged, as in a close case insect pests make rapid progress and soon disfigure the young plants.

IPOMÆA THOMSONIANA. This white-flowered *Ipomæa*, like its ally, the well-known *I. Horsfallii*, will not strike from cuttings, but can notwithstanding this be readily increased by grafting the shoots on pieces of the root of any allied kind, *I. Horsfallii* or *Batatas paniculata* for choice. The operation is very simple, being the same as that above recommended for the *Ficus*. After this the plant must be potted sufficiently low down to cover the point of union. Then the grafts should be placed in a close case till a union is complete.

SMALL SEEDS.—In the case of plants raised from small seeds they are often very tender and fragile, when it is necessary to prick them off, and consequently the operation is rather a delicate one. The mortality which often takes place soon after the young plants have been pricked off is frequently caused by want of attention to a few simple rules, one of the more important, and yet the one that is most frequently overlooked, being to press the soil around the roots, for by many a hole is made with a pointed piece of wood, then the roots are dropped into it, and the surface of the soil is just closed up around the collar of the plant, thus leaving the roots in the cavity made by the dibber only partially closed. The better way to prick off seedlings of a very minute character is to take the pots or pans, and having filled them with soil to within half an inch of the top finish off the surface with a little very fine compost. After the pots are prepared in this way, they should be watered and allowed to stand about an hour before using. Then the actual pricking off is performed by holding the dibber in a perpendicular manner and making a hole in the soil to the depth required, after which the plant must be placed in position and secured by putting in the dibber exactly as before, at about a quarter of an inch from the seedling, and slightly pressing the soil towards it. By these means there is no cavity left to cause the plant to perish, and it then grows away without check. Of course, considerable care is needed in other matters, such as watering, shading, &c. To facilitate the handling of very small seedlings a piece of wood about the size of a penholder, with a small cleft in one end, is

very useful for lifting up the minute plants without bruising them, and the dibber should be fashioned from a bit of Box or other hard wood, as it makes a much cleaner hole than if made of a soft wood.

WISTARIAS.—Unless seeds are obtainable, the only satisfactory way to increase the *Wistaria* is to graft it on portions of its own roots. The roots should be prepared as above recommended for grafting the *Ipomæa*, and the operation carried out in the same way. Roots of the common kind are available as stocks for the white and double-flowered variety, which last, by the way, I have never bloomed in a satisfactory manner. *W. multijuga* will also succeed on the same stock.

RHUS GLABRA LACINIATA. Last autumn having occasion to remove an established plant of this I took off a few roots the thickness of a pencil, and having cut them up into pieces about an inch long, dibbled them into a pan of soil just deep enough to cover the upper part of the root. The pan was then placed in a gentle heat, and now a quantity of young plants are already pushing up, thus showing how well this beautiful fine-foliaged subject can be increased by means of root cuttings. T.

REV. H. HARPUR CREWE.

The Rev. H. Harpur Crewe, twenty-three years rector of Drayton-Beauchamp, near Tring, was a most enthusiastic and successful gardener, his previous scientific training as an entomologist

REV. HARPUR CREWE. Engraved for THE GARDEN from a photograph.

having been of great advantage to him. His knowledge of hardy plants, especially bulbous ones, was extraordinary. Among his favourites were the *Narcissus* family. In 1882, in company with Mr. Maw, he visited Spain in search of bulbs, and spoke with delight of places where "there were almost as many leaves of bulbous plants as blades of Grass." The excursion was a success, but the very hard fare and exposure were perhaps bad for him, as he was previously not in strong health. He was for some time chairman of the floral committee of the Royal Horticultural Society, where his knowledge was most valuable. He frequently came up to the writer the day before the committee meetings and gave most useful hints when looking over the gardens. His gentle and kindly disposition endeared him alike to young and old. His death on the 7th of Sept., 1883, caused a blank in the gardening world which cannot be filled up. GEORGE F. WILSON.

Giving localities.—Can you not make your correspondents give some idea of their whereabouts, especially when speaking of hardy plants? The week before last one correspondent spoke of *Wachendorfia* as quite hardy "here," and another of the American Bramble "with us," but whether "here" or "with us" was in Madeira or Kant-

schatka they did not say. I know there are valid objections always to giving a name, but some indication of locality should be given.—W. G. M.

STOVE AND GREENHOUSE.

T. RAINES.

BOUGAINVILLEA GLABRA.

INSTEAD of this serviceable summer-flowering plant being catalogued and generally treated as a stove plant it ought to be classed as a greenhouse and conservatory plant, and grown as such. It certainly grows and flowers abundantly under stove treatment, but it is far more effective and beautiful in a greenhouse or conservatory, in which positions it is usually more richly coloured and remains much longer in an attractive condition. At one time we had two strong plants in our mixed plant stove, and by way of an experiment one was shifted about this time of the year into a greenhouse. So well did it grow and flower, that we decided to transfer the other plant to the conservatory, also with most satisfactory results. In both instances the plants were growing freely after being pruned and started afresh, but although only a small mass of soil could be preserved about the roots, they soon recovered from the severe check administered and flowered grandly the same season. I mention this in order that others may be induced to transfer their specimens to a cooler house, even if they are considerably advanced in growth. It may be necessary to keep trained exhibition plants in large pots, but for ordinary purposes they succeed much better out of pots. Even a tub is preferable to a pot, the roots being less liable to suffer for want of water in these, and a few hours' neglect in that respect usually ends in the loss of a great proportion of the leaves. We prefer to plant in narrow pits formed with loose bricks. A small pit 2 feet square and 2 feet deep, the single walls of bricks being neatly keyed together, is large enough and strong enough to hold sufficient soil to support a plant covering the end of a greenhouse. These walls of loose bricks are easily built and as easily taken down again, and very much simplify the necessary annual process of removing much of the exhausted soil from the roots and replacing with fresh. The proper time to renew the soil is when the plants are breaking afresh, this in a greenhouse being early in April. Good fibrous loam, a sprinkling of sand, and a slight addition of well-rotted manure or a little leaf soil is a suitable compost for *Bougainvillea*. This should be made firm with the idea of causing a floriferous rather than an over-luxuriant flowerless growth. When well established in a limited pot, pit, or box of soil, they, during the growing season, require abundance of water at the roots, and occasional supplies of weak liquid manure are also beneficial. We usually close our greenhouse early in the afternoon and syringe the occupants of the house freely, this, besides creating the desirable moist-growing atmosphere, also tending to keep down red spider. When the *Bougainvillea*, as well as tuberos *Begonias*, *Fuchsias*, and other plants are well into bloom, air is left on night and day, more or less according to the state of the weather. We have plenty of *Bougainvillea* bloom in July, and the last is usually cut in November. What I consider the

BEST POSITIONS for this plant are either the ends of a span-roofed greenhouse or against a back wall of a lean-to or three-quarter span-roofed house, the main branches being trained thinly and kept properly secured to the wires, from which will depend the long flowering shoots, the whole forming a gorgeous drapery not easily surpassed. Innumerable lovers of plants have seen and doubtless admired the formal, globularly-trained specimens at flower shows, but only a comparatively few have any conception of the great beauty of the *Bougainvillea* when growing and flowering in a free and but slightly restricted state. We have two specimens growing at the north end of a span-roofed house, and the wires being strained across at some distance from the glass, the plants, when at their best, are wonderfully effective, whether viewed from the inside or outside of the house. At Loughat they

have two very large plants growing in a narrow pit at the back of a three-quarter span-roofed house, these being spread over a trellis from the ground up to within a short distance of the roof. During the summer and autumn wagon-loads of long branches of bloom might easily be cut from them, and nowhere else have I seen it so fine. In the conservatory at Orchardleigh, near Frome, Somerset, there is another fine old plant, but this is trained thinly over the roof. Each winter, or after the growth is properly ripened, all the old flowering wood is cut hard back to the main branches; young shoots follow in abundance, gracefully hanging from the roof, and remain for a long time in bloom. The *Bougainvillea* is also well adapted for covering pillars, and we have had it very effective thus trained. In all and every case it must have plenty of light, but not fierce sunshine, anything overhanging it or smothering it in any way soon injuring and otherwise impairing its usefulness. It is not too late to order a plant or plants from a nurseryman, and if fairly strong plants are procured these will make good progress and give some flower this season. They require considerably less water in the late autumn months, and during November onward very little should be given them, the aim being to well ripen the growth without destroying the roots, and causing the wood to shrivel. In February all the weakly growths should be cut well back and the stronger ones shortened; while in the case of old plants that have well furnished the space allotted to them, all lateral growths should be cut hard back to the main branches. W. L.

Rhododendron multiflorum. This is noteworthy among the vast number of greenhouse Rhododendrons from the profusion with which it will bloom even in a small state, as neat little bushes in 5-inch pots are just now quite a mass of flower. It is a free-growing kind, forming a compact, much-branched bush, and the blooms, which are borne in good-sized clusters, are individually about a couple of inches across, and of a delicate mauve tint. The edges of the petals are also prettily crimped. Though this Rhododendron cannot be compared with many of the others for grandeur, it is still one of those kinds that when grown under favourable conditions can be relied upon to flower well. Its compact habit and free-flowering qualities have commended it to the hybridist, and between this and *R. Edgeworthi* several hybrid varieties have been raised, all characterised by a dwarf, free-flowering habit, but with blooms more nearly resembling *Edgeworthi* than *multiflorum*. The principal of these are Countess of Derby, Duchess of Sutherland, Countess of Sefton, Lady Skelmersdale, and Mrs. James Shawe. They are all pure white kinds with very beautiful sweet-scented blossoms.—H. P.

Phyllanthus nivosus.—This is a very pretty stove plant of a loose habit of growth, with dark coloured wiry branches and neat pinnate foliage. The flowers are insignificant, and its claim to recognition consists in the prettily variegated leaves, which are mottled with white and green in varying proportions, some being almost white, while others are nearly green. The young foliage on the upper parts of the shoots is, generally speaking, almost white, but at times suffused with a pinkish tinge. There is another kind (*roseo-pictus*) in which the variegated portion of the leaf is heavily suffused with pink, or when well exposed almost red. Like the last, a prominent feature of this is the irregular markings of the leaves. There is yet a third kind remarkable for the colouration of the foliage, viz., *atropurpurea*, the leaves of which are of a purple hue. However, when young and well exposed to the light, they are almost crimson in tint. These different kinds of *Phyllanthus* are of the easiest possible culture, for they strike without any difficulty from cuttings and grow away freely. If pinched back two or three times during their earlier stages they form neat little plants, which are very useful in many ways. At the same time their loose style of growth admits of their being employed for covering a screen, pillar, or similar place, but in any case the temperature of a stove is

necessary to their well-doing, and it must be in as light a spot as possible.—H. P.

Anthurium Andreamum flore albo. In the last number of the *Paris Revue Horticole* is a note descriptive of the above-named interesting and beautiful novelty, which, when propagated and distributed should be a great acquisition to all collections of stove plants, and a charming companion to the beautiful and almost perpetual blooming type form. This novelty has been raised from seed by a Viennese horticulturist, named Herr Mastner, and is said to possess a pure white spathe of the same texture and pitted appearance as in the type, with a brilliant red spadix, which should form a beautiful and striking contrast. This novelty should also prove useful as a parent, from which, by careful hybridisation, may be obtained still more beautiful forms.—W. E. GUMBLETON.

Aotus gracillima.—This very handsome greenhouse flowering shrub is now at its best, though, if retarded during its earlier stages, it may be had in bloom later on. It forms a much branched bush, with long, slender, wand-like shoots, bearing for a considerable portion of their length small Pea-shaped blossoms. The flowers are of a bright orange-yellow colour, suffused with crimson at the base. It is a delicate rooting subject, and requires a soil largely composed of sandy peat, and must never be allowed to become too dry; indeed, the treatment accorded to the so-called New Holland plants (once so popular) will suit it perfectly. It can be increased by cuttings of the young shoots that are produced when a plant has been cut back after flowering. The pots for their reception should be well drained, and filled firmly with sandy peat. After the cuttings are inserted they must be covered with a bell-glass till rooted.—T.

Mackaya bella.—As far as growing is concerned this is a plant of the easiest possible culture, but if kept in a green and flourishing condition it flowers at best but sparingly. To bloom it well a liberal treatment should be followed during the summer months, and towards autumn the supply of water may be lessened, and throughout the winter it must be kept almost dry. This mode of treatment causes the foliage to lose much of its freshness, yet, at the same time, it is the only course available to induce the plant to bloom. If the plants are placed in a genial temperature, such as that of an intermediate house, and watered they will quickly start into growth, and push forth their flowers. The blooms are borne in racemes, each consisting of a dozen or more flowers, the individual blossoms being somewhat bell-shaped, and nearly a couple of inches in diameter. Their colour is a kind of deep mauve, beautifully veined with purple. This *Mackaya* has been in cultivation for some years, but it is very rarely met with, and still more rarely flowered; though, given suitable treatment, it is not difficult to bloom. When in bloom it is so attractive and distinct from the generally cultivated stove or warm greenhouse plants, that it certainly merits more extended cultivation.—H. P.

Cinerarias. Visitors to Burnham Beeches or the grand old domain of Dropmore might just now do worse than call in at Woodside, Farnham Royal, where Mr. James has a truly wonderful show of *Cinerarias* in bloom. Woodside is just on the east side of the Beeches, and lies on the direct road from Slough to Dropmore. It is a very elevated, airy situation, where the air is pure and sweet, and the light is bright and plentiful. Here in some long span houses may be seen in full bloom some 2500 well-grown plants, grouped as far as well can be in colours, producing in this way a far more striking effect than is found when all sorts of colours are mixed up indiscriminately. The strain is marked by the robust medium height of the plants, the fine form, substance, and great size of the flowers, and the wondrous variety of coloration seen in them. A greater quantity of light colours has this year been introduced; whilst the fine average quality has been well maintained. It is to be deplored that Woodside is so difficult of access, as the show is one which might well tempt hundreds to visit it. As the plants are being grown to produce seed, of

course all bloom themselves thoroughly out; hence the blooming season is a prolonged one. The flowers, seen, in spite of their high breeding, to be full of pollen, and thousands of bees busily revel in it on sunny days. It seems evident that decadence in the *Cineraria* as a greenhouse flowering plant is very remote indeed.—A. D.

Alonsoa incisa. Where a supply of flowers has to be maintained throughout the winter months this old-fashioned plant is one of those that will be found useful for in a genial temperature it will keep flowering for months, and is by no means particular in its requirements. The blooms are borne freely on the points of all the shoots, and though individually they are only about half an inch in diameter, they are disposed in a many-flowered spike, so that when at their best they are very attractive. Cuttings taken in the spring strike readily enough and do well grown on under the same conditions as *Eupatoriums*, *Salvias*, and other winter-flowering plants, but being less vigorous than either of these two the *Alonsoa* does not require so much pot room.—T.

Thunbergias.—These, when treated as greenhouse annuals, are very interesting and showy; the varieties *alata* and *alata alba* are two of the best; the former, with petals of a rich orange colour and black centre, is very effective either when grown in such a manner that it hangs down over the fronts of the stages, or trained upon small balloon-shaped trellises. They flower during the months of July, August, and September. To have plants in flower in July, seeds should be sown during the early part of March; sow the seed in pans in sandy soil, and place them in a hotbed or vinery at work. When the roots reach the sides of the pots, transfer them into their blooming pots; those intended for draping the fronts of the greenhouse stages may be grown in 12-inch pots, and for larger specimens 6-inch or 8-inch pots will suffice, using a fairly rich compost. As soon as this shift takes place, the trellises should be fixed in the soil, so that the young growths may be secured to their permanent positions; do not stop the shoots; gradually immerse the plants to a lower temperature until they can be placed in an ordinary greenhouse. They must not be allowed to suffer for want of water, as red spider will quickly disfigure the foliage. Liquid manure may be applied with great advantage. E. M.

Rudgea macrophylla. This South American stove shrub is now in flower, and, considering the beauty of its blossoms, as well as their distinct character, one would expect to find it grown more than it is at present. It is a thick-stemmed sturdy-growing plant, sparsely branched and clothed with deep green leathery leaves. The individual blooms are not unlike those of an enlarged *Bouvardia*, but are of quite a fleshy substance and borne in large globular heads on the ends of the branches. Coming from the neighbourhood of Rio Janeiro, this *Rudgea* requires the temperature of a moist stove, as if grown in a cooler structure the foliage soon loses its deep green tint and becomes of a sickly hue. Its propagation is by no means easy, and to this circumstance is no doubt due the fact of its continuing to be such an uncommon plant in gardens. The most successful way to increase it is to cut back a plant after flowering, and as soon as the young shoots that are then produced have acquired a woody texture, they are available as cuttings. The cuttings should be inserted singly in small pots, and plunged in a gentle bottom heat in the stove. They must be kept close and shaded till rooted.—H. P.

Monstera deliciosa. The fruit described by "G." in THE GARDEN (p. 328) under this name with the synonym of *Torneelia fragrans* is, according to his account, very different from the *M. deliciosa*, which under that name and the synonyms *Philodendron*, *Scindapsus*, and *Pothos* (I cannot find *Torneelia* in Pritzels, Stendel, or any other book in my possession), I have cultivated for many years, ripening annually about a dozen of its truly delicious fruits, which, instead of being about the length and shape of a Pine-apple, and when ripe pinkish in colour, are with me cylindrical in form and about 10 inches in length by 2½ inches in diameter, externally green

throughout its growth, without the slightest tinge of pink; it ripens gradually from base to point; as it ripens the rind separates from it in hexagonal plates, exposing a semi-transparent, whitish cellular pulp, which when ripe swells above the level of the unripened part and separates easily from the solid core. Everyone who has tasted it without exception, according to my experience, describes it as one of the most delicious fruits; it is perfectly wholesome, but occasionally leaves for a short time a slight pricking sensation in the mouth. I grow it in loam without any admixture in a bed with two 4-inch pipes underneath in a very cool stove. In the growing season it should have plenty of water, and occasionally some liquid manure, or a top-dressing of chemical manure. The fruit ripens in exactly twelve months from the time of flowering. The Banana flourishes and ripens its fruit annually in the same bed under the same treatment.

EDMUND TONKS.

Bouvardia rosea multiflora.—Judging from the very limited number of flowers one sees of this grand Bouvardia, it is not as well known as it deserves to be. During a recent visit to the establishment of Messrs. Lonsdale & Barton, Chestnut Hill, Philadelphia—where several nice things are always to be found—I saw this Bouvardia in very fine bloom. It has the largest truss of any known variety and of a beautiful soft rose tint, and must certainly be valuable to the florist requiring mixed flowers. I also saw and examined some new seedling Carnations of the Grace Wilder class, among which are two very promising varieties. Their Roses, particularly the Teas, are in fine condition.—J. N. MAY, in *American Florist*.

DeGraw and Hinze's white Carnations.—These two Carnations are receiving considerable attention at present. When well grown they are both good, but they require different treatment. DeGraw succeeds best planted in not too highly enriched soil and fed with liquid manure as the flowering goes on. The best house of Carnations I have ever seen was one in which this variety was grown. It belonged to John Thorpe when he was in Cleveland. It was simply wonderful the number of perfect flowers he cut from this house, and the above was the treatment he gave it. We then often talked Carnation culture over, and he was fully convinced that stimulating with liquid manure at the time the greatest strain is on the plants, viz., when producing their blossoms, was the main point in his success. By following this method of culture since with this variety I have had good success. I would much rather prefer growing Hinze's white. Although not of the purest white, it produces large flowers of good shape and exquisite fragrance generally on long stems. In order to succeed with it, however, I find that it requires strong rich soil with abundance of water when freely growing, and perfect drainage to allow it to pass off freely. The same treatment is suitable for Buttercup; they succeed well together in the same house under the same treatment, but give Buttercup the treatment suitable for DeGraw and but little success will be had; suitable soil and conditions make it one of the most profitable varieties, while unsuitable soil and conditions make it the most worthless. M. MILTON, in *American Florist*.

SHORT NOTES.—STOVE AND GREENHOUSE.

Fumigating with tobacco.—Is there any way of using Tobacco besides smoking the whole house? I have a Marechal Niel Rose covered with greenly on the roof of a large greenhouse, and it is impossible to move all the plants for smoking it.—H. R. C.

Tacsonia exoniensis.—What a glorious conservatory climber this is! I met with it last summer in a spacious conservatory where it was doing grandly. There were three or four specimens planted out in a raised bed, and they had made a very free growth and were flowering with many yellow freedom. All the pruning given was simply to trim the leading shoots in about the commencement of the winter. For freed in of bloom and general effectiveness I place it before *T. Van Volxemii*.—R. D.

Boronia megastigma.—I send for your inspection a plant of *Boronia megastigma*. This, I think, is very much neglected, as there is nothing much more beautiful in the way of perfume. The plant sent was grown in quite a cold house with *Beatis* and *Leschenaultia*.—W. B.

—A densely flowered plant of this most useful class.

These plants deserve more attention at the hands of cultivators than they at present receive, as they are of so very easy management, and will well repay any trouble taken with them.—Ed.

CARNATIONS IN AMERICA.

SWEET and lovely flowers, thrifty and copious, but often capricious. E. G. Hill with me is splendid; the flower is larger than that of Portia, and like it does not burst. Glowing Coal, a seedling of Portia, and which Louis Siebreck grows in large quantity, is very like E. G. Hill. Portia is very bright and copious and the stems are long, but the blooms are somewhat small. Marquis of Lorne, a scarlet I had a few years ago from Andover, Massachusetts, is of stocky habit and free blooming; the flowers are a good deal larger than but not so long-stemmed or so bright as those of Portia. Marshall P. Wilder is a new one I got a year ago from Hallock & Thorpe. It has very large, highly fragrant, full double flowers, scarlet, with crimson stripes. During the last two winters Charles Henderson was the most prolific Carnation I had, vigorous in growth and with sheaves of flower-stems. This season it is not so good; and, curiously enough, *La Purité*, which for the past two years was only middling, is extremely luxuriant this winter and has blooms like little Paeonies. Two years ago Lydia was capital, last year poor, this season good. Hinze's White is the best of its class that I have tried; when well handled its blooms are large and perfect in shape. I cannot do anything with Peerless.

Three years ago, one of the finest lots of white Carnations I ever saw was a houseful of DeGraw, with C. L. Allen, of Garden City. But it is one of the most unsatisfactory sorts with me. Crimson King is always a mainstay. Black Knight is very good, and now is a popular market variety. It is bright, and keeps its colour well after being cut. Fred Johnson is one of the best of its class, copious, long-stemmed, and of pleasing colour. I never yet got Buttercup healthy enough to give me satisfaction; I presume when growers give it more rest it will become better favoured. Miss Joliffe is very pretty and much liked, but I should not care to depend upon it alone; I have sometimes found it uncertain. Among yellows, Sensation must get a prominent place on account of its large blossoms. Kaiser Wilhelm grows and blossoms freely enough, but many dislike the colour. Gibbons is the biggest and most fragrant dark crimson Carnation that I know of. It is of tall, vigorous habit, copious enough in its season, but I did not find it perpetual. It is grown in some private gardens around Boston, but so far as I am aware, not in the trade. I am out of it and wish to get it again, but do not find it advertised. One Boston grower writes me that "it would not pay us to grow it for less than 1s. a bloom." Petunia is a full, but ragged flower; still the ladies are very fond of it. Mrs. Harris has a vigorous constitution and large, perfect flowers; some like it, some do not. I do not think it will pay the cut-flower florist to grow an extensive variety of Carnations; better confine himself to two or three sorts that he finds are the best and most profitable with him.

So long as the Perpetual Carnations keep on blooming in ample quantity it does not pay me to also force the hardy Pinks. These last come in well from March till May. I find that the after-success of Carnations depends much upon the cuttings from which they are propagated. Stout, clean, healthy, stocky cuttings should always be selected.—W. FALCONER, in *American Florist*.

Cobæa seedlings.—All know how difficult it is to raise more than a very small per cent. of Cobæa seed, and as I have just tried an experiment which has proved remarkably successful, I will describe the method used. I placed some Sphagnum in the bottom of a 7-inch pot, covering with a little drainage; on this placed a 4-inch pot so as to bring the rims of equal height, and filled the space between the two with sand. I filled the inside pot one-third full of drainage, covered with rough soil, and filled even with the top with sand. Twelve seeds were sown very shallow, on edge, and after

moistening, covered with a flat glass and placed on an inverted saucer in a drum connected with a stove. Water was afterwards given only to the outer layer of sand, and from the twelve seeds I have eleven healthy plants in their second leaf. L., in *American Florist*.

SEASONABLE WORK IN PLANT HOUSES.

STOVE. TEMPERATURE AND SHADING.—In warm stoves, and also in houses containing plants that require an intermediate temperature, the heat should be increased to something like the maximum summer warmth, as there is now enough daylight to admit of this. As to shading where a general collection of stove plants is grown, there will be some that will not do with exposure to the sun, whilst others are benefited by all they can get. Provided the houses stand ends north and south, and the glass is free from burning lenses, such things as Allamandas, Bougainvilleas, Dipladenias, Exoras, Crotons, and some others do not require shade, except when in bloom. It is best to locate the plants that require shade at one end of the house where the necessary protection can be provided for them. But under this kind of treatment the atmosphere must be kept well charged with moisture by throwing water about the floors and side stages freely in the daytime, and also by giving less air than some growers suppose to be necessary. In well constructed houses where the plants are kept well up to the glass, much less air is requisite than often looked upon as needful.

BOUVARDIAS.—Young stock struck from cuttings at the beginning of the year and afterwards moved into little pots will now require more room. They may be put into 4-inch pots, giving them good loam to which add some leaf mould, rotten manure, and sand. The plants may again be stopped, pinching out the points of all the strongest shoots; if this is not attended to whilst they are small they will not be sufficiently furnished at the bottom. An intermediate temperature is still necessary; if the plants are not pushed along early in the season they do not attain sufficient size before the end of summer to admit of their giving the requisite amount of bloom. Plants that bloomed late, and were cut back after flowering, and have now broken into growth, should be shaken out and re-potted, regulating the size of the pots according to the size the plants are required. Bushy specimens from 3 feet to 3½ feet through may, with liberal feeding, be grown in 14-inch or 15-inch pots. In large conservatories these are more effective than the ordinary sized examples usually met with, but not so useful for general purposes. Bushy-headed standards, 2 feet or 3 feet high, are also serviceable for standing amongst lower growing things. Where these are required all that is necessary is to select plants of any of the stronger growing varieties that have got a strong shoot springing from the base, and cut away all the others so as to direct the strength into the single stem, rubbing off any growths that may appear on it until the requisite height is attained, after which pinch out the top, repeating this with the shoots that are subsequently made until the heads are sufficiently furnished. In the case of Bouvardias that are to be grown in beds in pits and frames, these may now be planted out, providing there is the means of giving them a little warmth. Where this cannot be done it is better to defer turning them out for a month or so.

GREENHOUSE POTTING HARD-WOODLED PLANTS.

—All young stock that requires more root room should be potted without delay. This operation is often deferred until later on, under the impression that it is better to wait until the roots are more fully in motion. But it is much safer to bring the work to a close before the weather gets very hot, as then the dry condition of the air is such that the plants are more likely to feel the effects than when the state of the weather makes it possible that the house or pit in which the newly potted stock is located can be kept all but closed for a week or two after the operation without the temperature rising higher than desirable. There is nothing tends so

much to help the roots to lay hold of the new soil as a close, moderately moist atmosphere; to allow large volumes of dry air to come in contact with the plants just after their roots have received the check that inevitably follows repotting is to court failure. One of the worst effects of potting in very hot weather is, that the plants require watering before the roots have had time to move, which it is well to avoid. This matter of early potting refers to all plants that have not more than attained quarter specimen size, for even if they are likely to produce a considerable amount of flower during the next month or six weeks, it is better to pot now than wait until the blooming is over. Care should always be taken in potting hard-wooded greenhouse plants to see that they are in right condition for moisture, as if the balls are in want of water at the time of shifting it becomes necessary to give it sooner afterwards than is desirable. The day before the plants are moved they should be closely examined to ascertain their state in this respect, watering such as require it, and allowing time for the moisture to pass off before potting. It is equally necessary to see that the soil used is in the proper condition; if it is too wet the roots do not take kindly to it, and if drier than it should be kept watering becomes necessary too soon. In the case of all hard-wooded plants that are potted in spring after the sun has got a good deal of power, the atmosphere should be kept moist for two or three weeks by throwing water about freely on the floors and spaces under the stages; this with shade overhead when the sun is bright helps the roots to at once lay hold of the new soil.

AFTER TREATMENT OF FORCED ROSES.—I made a few remarks some time back on the treatment of Tea Roses that had been forced early in the winter. Plants that have been subjected to forcing later on require equal attention, as much depends on how they are managed whether they will be of further use in this way or not. If the treatment they receive is such as is calculated to restore the strength and vigour that are taken out of them by being forced into flower at a time when they would naturally be at rest, there is ample evidence to show that not only will plants that are so used be able to hold their own for a number of years, but they will go on improving. This applies to both the Hybrid Perpetuals and the Tea varieties, especially the latter, though from the natural ability which they have to yield successional flowers the weakening effect of forcing is proportionately greater. Plants of the perpetual or of the summer-blooming sections should, as soon as they have done flowering, be moved to a spare pit or other structure where they will get plenty of light, and where a genial atmosphere that will encourage both root and top growth is maintained, giving manure water or top-dressings of concentrated manure, and taking means to keep the foliage free from insects and mildew. Give air in the daytime according to the state of the weather; for the Teas a little heat for a few weeks until the nights are warmer will be an advantage, shading slightly when the sun is powerful. Though there is now less difference between the temperature of the external air and that of the house or pit in which the plants are located than there was in winter, it is nevertheless still necessary to be careful when giving air not to subject the foliage to cold draughts, otherwise an attack of mildew is certain to follow. In private gardens want of room frequently necessitates the plants being turned out of doors later on; this will do no harm to the perpetual and other strong-growing sorts, but in the case of the Teas, if they can be kept under glass for a considerable time yet, or altogether, with a continuance of the attention in other matters advised, they will be found to have gained correspondingly more strength at the close of the summer. During autumn they should have abundance of air so as to hinder growth as far as possible. From the persistency with which Tea Roses keep moving if the temperature is not bordering on frost, they may be said to be perpetual growers.

VALLOTAS.—Coming into flower as these showy bulbs do in the latter part of summer and autumn, when blooming plants are not plentiful, it seems

strange that they are not more generally met with in greenhouses, especially when the fact of their rapid rate of increase is taken into account. Plants that have been at rest and kept somewhat dry at the roots through the winter will now be moving into growth. In the case of any that require more pot-room a shift may be given them; but as the roots will be already at work, it is better not to attempt separating the bulbs, merely getting away the smaller ones and the little bulblets that the plants when strong produce in quantity. The former may be placed three or four together in pots proportionate to their size, whilst the little ones may be put an inch apart in pots or pans, inserting them about half their depth in the soil, pressing it firmly about them. Whether the old plants require a shift or not, the little bulblets are better removed. When repotting, it is well to remove as much of the surface soil from the balls as can be done without disturbing the roots. Good rich loam answers for these plants, mixing as much sand with it as will ensure its retaining porosity. Pot firm, and see that the pots are well drained. The plants require plenty of light, especially whilst their growth is being made, and sufficient air to give solidity to the leaves. Old specimens that do not need moving will be much benefited by frequent applications of manure water, being careful not to use it too strong. T. B.

EDUCATION OF GARDENERS.

WITH considerable interest I read the paragraph in THE GARDEN (March 26, p. 271) relative to Mr. Penny's orphanage scheme. "An Orphan Boy" says:—

The better education of gardeners has been everybody's cry since he remembers; it is more needed now than ever, and would benefit both the parents and the children, and now is the opportunity.

I have volumes of garden periodicals which were issued twenty years ago, containing articles on the education of gardeners, and I would say for myself that I always felt as an under-gardener the need of some work dealing specially with subjects coming within the range of the garden. In my opinion there is a vacancy which the ordinary gardening periodicals fail to fill. It is not desirable they should do so, as they have their sphere and work, but there is much in them which might almost be termed useless reading for a young man. Mr. London issued a work intended as a self-help for young gardeners, but, of course, it is now out of date, and I daresay out of print, and I beg to suggest the necessity there is for a similar work, or what I think would be much better—a weekly or monthly periodical, which might be entitled "The Under-Gardener." I may be mistaken, but I feel confident that hundreds—not to say thousands—of young men would hail with delight the advent of such an organ, in which they could learn the elements of the various sciences connected with their life's pursuit. In our profession the young men are few and far between who have received a technical education; moreover, many of them occupy situations in country places, where they have no facilities for acquiring knowledge, while their means are too scanty to enable them to purchase many books, which, as a rule, are rather expensive. A magazine treating on arithmetic, botany, chemistry, dynamics, evolution, electricity, geography, geology, geometry, heating, hydraulics, hydrostatics, &c.; also biographies of eminent gardeners, recreative natural history, and the thousand-and-one other subjects which would naturally find places in its pages—which, of course, would be open to correspondence and the discussion of its various leading articles, is, I am sure, much needed.—H. J. H.

* * * We print this letter from "H. J. H.," but no good would come from such an enterprise as he sketches. A gardener should learn his own business well, and he has enough to do if he does that. Gardening is now an art of great and varied scope, and offers opportunities enough to exercise the most gifted mind. If gardeners want to learn "chemistry, dynamics, evolution, electricity, hydrostatics," by all means let them do so, but they had better learn them in the usual way; but we think they should not learn them. The best gardeners that we have ever

known were simple observers of Nature, and did not know even the meaning of these terms. The idea of a man mastering a science like chemistry, or even getting his head full of the technical expressions of some of the subjects mentioned by "H. J. H.," and afterwards having time and thought for the daily practice of gardening now is too much. And what on earth does a gardener want with electricity, hydrostatics, or chemistry?—Ed.

GARDEN FLORA.

PLATE 593.

MILTONIAS.

(WITH A PLATE OF *M. SPECTABILIS* AND *M. MORELIANA*.*)

THE genus *Miltonia*, named by Lindley in honour of Viscount Milton, afterwards Earl Fitzwilliam, a zealous patron of horticulture, is by no means an extensive family. Some of the species contain the most beautiful of the whole Orchid family, whilst all the varieties are well worthy of cultivation. *M. spectabilis* and its variety *Moreliana*, which our artist has so admirably depicted on the accompanying coloured plate, are perhaps the best known of the species, and are amongst the oldest of the genus in cultivation. Upwards of forty years ago plants of *M. spectabilis*, some 2 feet or 3 feet in diameter, were to be found in the gardens at Bothwell Castle, in Scotland, and others equally large existed in the collection of the Rev. John Clowes, of Broughton Hall, near Manchester, and in various other places; but as these kinds are very subject to become of a sickly yellow hue both in the pseudo-bulbs and foliage when grown with full exposure to the sun, they for a time become unpopular. Now, however, since it has been proved that *Miltonias* can be grown successfully, the various species and varieties are eagerly inquired for. Nearly all the *Miltonias* are natives of Brazil, and to have them of good colour they should be kept at the warm end of the *Cattleya* house exposed to good light, but shaded from the sun. They enjoy an abundant supply of water, both to their roots and over their foliage during summer. The supply of water must be diminished during the winter months, but the plants must not be allowed to become dry at any time of the year. The drainage for *Miltonias* must be exceptionally good and open, whilst the soil best suited for them is about equal parts of fibrous peat and *Sphagnum* Moss, with some nodules of charcoal added. We have also found a little soot mixed with the water applied to the roots highly beneficial in giving a deep green colour to the pseudo-bulbs and leaves. *M. Moreliana* and *spectabilis* produce a single flower only on a stem, as also does *M. spectabilis* bicolor. The flowers of *M. spectabilis* bicolor are white, slightly blotched with violet at the base of the lip; whilst in the variety radians the flowers are white, with several radiating stripes of magenta-purple at the base of the lip. All the *spectabilis* type are autumn bloomers. Other kinds, with large, flat flowers, are *Miltonia Roezli* and *Roezli alba*, *M. Phalenopsis*, and *M. vexillaria*, more familiarly known by the name of *Odontoglossums*; and *O. Endresi*, which is a rare species, somewhat resembling *M. Roezli*. The flowers, which are produced in winter and early spring, are white, with a rosy pink blotch at the base of each segment. It is figured in the *Botanical Magazine* under the name of *Odontoglossum Warscewiczii*. *M. Regnelli* is of erect growth, with a large, flat, rosy lilac lip bearing numerous flowers, the

* Drawn for THE GARDEN by H. G. Moon in the Royal Gardens, Kew, Sept. 15, 1886, and printed by G. Severoyne.

MILTRIA SPERMATOPHYTES, AND VARIETY OF BEETLES

sepals and petals of which are rosy white. The petals in the variety *purpurea* are rich crimson, suffused with magenta. *M. cuneata* produces an erect spike, bearing a raceme of five to eight flowers, having the sepals and petals chocolate-purple, tipped with yellow; lip white, tinged with pink. *M. Clowesi* and its varieties *major* and *Lamarckiana* are handsome plants, having many-flowered racemes, which are sometimes branched; the sepals and petals are deep yellow, transversely banded with large blotches of chestnut-brown; lip white in front, stained at the base with deep purplish violet. *M. Warszewiczii* is a very distinct plant, better known in gardens perhaps by the names of *Oncidium fuscatum*, *O. Weltoni*, and *Odontoglossum Weltoni*. It comes from Peru, and flowers in early spring; whilst nearly all the other species bloom in the autumn. This plant thrives best under very cool treatment. The spikes are much branched and bear sometimes as many as fifty flowers, which vary much in colour, but are usually olive-brown or cinnamon, tipped with yellow or white; lip brownish purple, white in front,

Miltonia candida grandiflora.

with a curious varnished-like spot in the centre. *M. candida* and *candida grandiflora* differ in having a convolute lip. This distinction is admirably rendered in the annexed woodcut. The spike is erect, bearing from five to eight flowers; sepals and petals reddish chestnut, edged and tipped with yellow; lip white, stained with purplish violet in the throat. It is an autumn-bloomer. Other kinds of *Miltonias* deserving attention are *festiva*, *Blunii*, *anceps*, *Russelliana*, and *Warneri*.
W. H. G.

Podophyllum peltatum. The American May Apple is not only a very showy plant when in flower, but from the peculiar singularity of its primary mode of growth each spring is a very desirable botanical novelty. Suitable for growing in any damp situation out of doors, or in good rich soil, it produces very showy, large white flowers, which may not inaptly be likened to a single *Camellia* flower. These are followed by pale yellow berries about an inch in diameter. The leaves, singular in form are entire, circular, and fringed,

and held aloft singly upon 6-inch stalks, somewhat resembling a nymphaea when unfolded. It is a singular fact that each leaf comes up out of the ground folded up as compactly as an umbrella. The plant, as its generic name implies, is translated duck-foot-leaved, owing to a fancied resemblance the leaves bear to a duck's webbed foot at certain stages of growth. The roots furnish the medicine podophyllin of recent introduction.—WILLIAM EARLEY.

KITCHEN GARDEN.

W. WILDSMITH.

RIDGE CUCUMBERS.

THESE are not so generally grown—or, perhaps I should say, so well grown—as they should be, considering their acceptability for salads throughout the summer and early autumn months. Probably the reason for such neglect of cultivation in many instances arises from previous failure, the result of neglect of attention to the plants in the earlier stages of growth, owing to the mistaken notion that because a plant is said to be easy of cultivation, we expect it to do without any attention at all, and then wonder at our failures. Common and easily grown plants, alike with the rarest and difficult to grow, will not thrive of themselves, but they will repay a proportionate amount of painstaking their cultivation, and if this be afforded to ridge Cucumbers, the produce may reasonably be expected to bear comparison with the best frame-grown Cucumbers. I say this advisedly, as for many years past, owing to want of frames and house-room in which to grow Cucumbers during the summer, we have had recourse to keeping up supplies from open-air ridges, and ours are really grown on such, for having neither frames nor stable litter to spare for hotbeds, we adopt the next best plan, which is a sheltered sunny bank or border; a trench of any length desired, and 4 feet in width, and a foot in

depth is then dug out, and in this we put lawn mowings and as many leaves as can be spared, to generate a little warmth to start the plants into growth; the plants would start without such heat, but they take longer time, and with our short summers every day gained is of advantage, and the additional labour involved in forming such a foundation is scarcely worth considering. Supposing, however, that neither litter nor lawn mowings are at command, the bed should be made after the ridge fashion; that is, the soil be thrown in line something after the form of the old way of growing Asparagus. By this plan the sun has full play on the ridge of soil, and, provided it is kept moist and the surface mulched with droppings (except being a little longer time about fruiting), there is really little to choose between them and those started with bottom-heat. The soil we use is ordinary kitchen garden soil, enriched with leaf soil and horse droppings, but this we supplement by always keeping the surface mulched with leaf soil or manure. We make but one sowing, and that during the second week of April, and of course they are raised in heat, potted off into 3 inch pots as soon as they are in the rough leaf, and again put in heat till the pots are full of roots, which they generally are early in May. They are then planted singly on the ridges 2 feet apart, and each plant is afforded the protection of a bell-glass till established in their permanent quarters, when they are gradually inured to bear full exposure by placing sprays of evergreen branches on the windward side of the plants. As soon as the plants have fairly started into growth they are closely examined to remove surplus shoots that

invariably form at the base, three shoots and the lead being the maximum we allow to remain, and all laterals that form on these are kept closely pinched out till the shoots have attained a length of 2 feet. A good foundation is thus laid for the formation of other shoots, which may then be of any number so long as there is no risk of overcrowding, which must always be avoided, as this, next to an attack of black fly, is the worst of evils. It is necessary, therefore, that a strict rule of periodical thinning out and regulating of shoots be adhered to, and once a week is not too frequent. As to parasites, black fly is the most troublesome, next thrips, then mildew, and last, green fly. Though it may not be possible to prevent attacks of such parasites, their power to injure is much less when the plants are in vigorous health; obviously, therefore, this is one way of fighting them. Another way to destroy fly and thrips is to syringe with tobacco water, and if once they can be got under, a syringing with soapsuds once a week will generally keep them down. Mildew is generally the result of a check in growth caused by drought or the opposite conditions, and its progress is therefore not so readily stayed. The most successful way to battle with it is to remove as many of the affected leaves and shoots as the future well-doing of the plants will warrant, and then apply a heavy dusting of sulphur; water the plants twice or thrice with clear manure water, and repeat the same if there should be any appearance of waning vigour. Above all, cut the fruit the moment it is of usable size, that no unnecessary impoverishment of the plants may take place—a remark that is equally applicable to healthy plants, that they may continue in a good fruitful state all the season. It is by these little details of culture—apparently unimportant in themselves—that success is assured.

HARDY BROCCOLI.

I HAVE not the pleasure of Mr. Groom's acquaintance, still I know him to be a practical man on most matters relative to horticulture, but when he tells your readers that not one market grower in a hundred uses the crowbar in planting Broccoli he is labouring under a great mistake, for it was in a market garden, or rather field, of thirteen acres that I first saw it done, and, to be concise, the field was rented by a Mr. Flicker, at Lesness Heath, Kent, where the above grower was located. This gentleman was a large grower of Peas, Broccoli, Gooseberries, and Potatoes something like thirty years ago. I may also mention that a Mr. Ives, a grower in the same locality, always planted Broccoli with a crowbar. I may tell Mr. Groom that it is not impossible to grow stocky, short-legged plants in close walled-in gardens, because we do it here, at Burghley, yearly.

Mr. E. Gribble says that he has grown Veitch's Model, and has never known it to fail. I have grown the Broccoli in question, and have always found it satisfactory in many respects, but I must say the flavour is strong and objectionable. I am much obliged to Mr. Gribble for his closing remarks, and shall book him for a packet of Broccoli seeds for trial with Model.

"J. S. W." tells us there is not such a thing as a hardy Broccoli. Well, the question comes, what is a hardy Broccoli, measured by the standard of "J. S. W."? I have this day counted two flats of Victoria late white Broccoli. No. 1 is inside the garden walls, which contains 865 plants, 18 being blank, while outside the garden wall flat No. 2 contains 380 plants, 20 being blank, thus showing out of 1245 plants only 38 are dead. Now, I do not mean to say that even the frost has killed these, nor do I say it has not. Would this Broccoli be called hardy by "J. S. W."? "J. S. W." also tells us that he could produce cottagers by the score that grow Broccoli of the best

quality, and as long as it can be had. Permit me to say, I can go further than that, and can produce cottagers that can not only grow Broccoli, but all kinds of vegetables better than one-half the gardeners of this country. If "J. S. W." wants a demonstration of the fact, I shall be happy to tell him where to go. There is another little item respecting poor Chou de Burghley that is scarcely worth notice; nevertheless I may say that it is the best Cabbage extant. In conclusion, I may say that Mr. Wright is the man that first discovered the Broccoli; personally, I have never represented it as a Broccoli.

Your correspondent "Hortus" tells us a good crown of leaves is a capital protection for Broccoli stems, but the stems are often safe enough while the crowns are frost-bitten. My dictum is that the frost catches the stems between the soil and the leaves. If "Hortus" will favour me with his address, I will enclose him a packet of Broccoli seeds, which I feel sure will settle the question.

R. GILBERT.

SPRING TREATMENT OF ASPARAGUS.

THE time has now arrived when the formation and renovation of Asparagus plantations must receive attention. Few cottagers care to cultivate Asparagus, but amateurs delight in having a good bed of it, and no garden under the charge of a professional gardener can be without it; in fact, in many gardens it is regarded as the most valuable crop of all, and a liberal supply of first-rate produce never fails to give the utmost satisfaction to all concerned. Forced Asparagus is a delicious dish, and from the end of April until the middle of June the open-air produce cannot be equalled by any other vegetable in season. Peas and other good vegetables may be late, but so long as there is plenty of Asparagus this absence will not inconvenience anyone; and I would strongly advise all who value choice vegetables at this time to grow as much Asparagus as they possibly can. It is no uncommon thing to see the most ordinary crops, the half of which will never be consumed or prove remunerative, occupy large quarters in vegetable gardens, while choice Asparagus is only planted and grown to a very limited extent; and I feel absolutely certain that were the Asparagus planted extensively to supersede the common produce, the result would be beneficial to all. I have long considered it a waste of all material to attempt to renovate an old Asparagus bed when the whole of the roots that remain only consist of a few at great distances apart. If there is only a blank here and there in the plantation it may be made up, but success will never attend the planting of a great many young roots amongst a few old ones, as the latter hinder the proper preparation of the ground for the reception of the young roots, and this is a very important point. Many Asparagus plantations fail through the soil in which they are planted not being properly prepared, and not a few also fail in the soil being too much prepared. Some have an idea that Asparagus cannot be too well done, and all kinds of useful, useless, and superfluous manures are put into the soil with the object of securing uncommonly fine produce in an unusually short time; but the result is more often failure, and then the cultivator cannot understand it, as the bed was so complete in its composition. Any ordinary good soil will grow first-rate Asparagus, and after applying the necessary manures and cultivation the less it is meddled with the better. The "Asparagus bed" is such a familiar term, that many who purpose beginning its culture would never expect to succeed with it unless the roots were planted in the orthodox bed; but this is wrong, as the old-fashioned, high-sided, neatly-cut-out bed is rarely patronised by good modern growers, but a good piece of ground is planted row after row, through and through, and there is then no ground lost by wide pathways between the beds, while the results are remunerative in the highest degree. If I had 150 new Asparagus plantations to make I would never think of giving one of them the form of a bed. The only soil to avoid in Asparagus culture is a heavy, wet, retentive one. The roots are very fleshy, and in the summer they will push out a long

way, but when winter comes they will not grow in a wet soil, and the greater part of them will die back until the plant is left with so few that growth the following season will be most unsatisfactory, if not quite a failure. This may lead those who have nothing but a heavy soil to work with to infer that their chance of growing good Asparagus is hopeless. Nothing of the sort, as the whole may be easily remedied by drainage or the addition of light material. In dealing with a heavy, wet soil, it should be trenched to the depth of 2 feet 6 inches, and a large quantity of ashes and any old rough material should be placed at the bottom of every trench. This will act as excellent drainage and improve the soil as well, and a quantity of sand or road-scrappings should be added to the soil near the surface. The quantity must be determined by the texture of the soil, but do not stint it in any case. This trenching and adding to must all be done before manuring begins, but as soon as these operations have been completed place a heavy dressing of manure on the surface and fork it well through the soil, and the piece will then be ready for planting. I guarantee that a quarter treated in this way would produce excellent crops of Asparagus for many years, but it ought to be understood that the utmost importance must be attached to the indispensable system of thoroughly preparing the soil before any attempt is made at planting, as once the roots are planted and established the soil should not be disturbed again to any extent for many years. The not uncommon plan of planting in a hurry in any kind of soil and letting the roots take their chance will never do in the case of Asparagus, but with a properly prepared soil and roots rightly planted they will succeed permanently in spite of everything. There are many gardens, however, where the soil is naturally adapted for Asparagus growing, and in these instances culture is very easy. In preparing to plant it is only necessary to manure the surface well, and add a little sand or general refuse. Horse droppings make the best manure for Asparagus, and of artificial manures, soot, guano, and salt are the best. Seaweed is also excellent, and wherever it can be obtained it should be used in preference to everything else. It may be dug into the ground like manure, and where the soil is poor horse droppings may be added to it. I do not, however, approve of dressing the ground with these manures and adding a quantity of artificial manure as well. Well-prepared ground does not require artificial manure at first, and this should only be applied in after years as a stimulant. In selecting ground for Asparagus, odd corners must be avoided and the best part of the garden devoted to it. Sun and air are very essential to the perfect development of the stems and maturing of the crowns. In planting the roots, great care should be taken that they are not allowed to shrivel or dry up when out of the soil. They may be transplanted most successfully from one to three years of age. In buying roots from a nursery, I would insist on their being packed in a little damp Moss, and they should not be allowed to remain a minute longer on the road or at the station than is actually necessary. Laying them in temporarily until their quarters are ready is a bad plan, as it is impossible to shift and re-shift them without injury. Of this I have had ample proof. When the young roots are home-raised and have only to be taken from one part of the garden to another, planting may be done without losing a single root, as they should be transferred without being out of the soil more than a few minutes. The roots are all star-like in form, and they may be crammed into a very small hole, but this is not beneficial, and the best way of planting is to allow them plenty of room to go in freely. Each hole should be taken out with a spade to the depth of 4 inches or 5 inches, and about 4 foot square. The root is then placed in without a twist, and free growth is sure to follow. In the bed system it was a general rule to plant 1 foot or a little more apart, and in a short time the top-growths became a crowded mass, but this had a direct tendency to lessen the strength of the shoots, and the best of all results are obtained by planting each root about 2 feet or 2½ feet apart from the other, and allowing the top growth unrestricted space. There is nothing

lost in this, as there will be as many heads cut from a root 30 inches from its neighbour as there would be from two roots in that space, and the size of the former heads will be much in excess of the latter; in fact, first-rate produce can only be secured from roots grown widely apart, but at whatever distance they may be put in, if they can be planted in wet weather it will be greatly in their favour, but if the weather is dry throughout the whole of the planting season, as it promises to be this year, water freely as soon as planting is done. One-year-old roots often succeed better than older ones, and the older they become the more risky is their transplanting; but, although they may be transplanted at three and four years old, none of the produce should be cut from them the first year, as the aim should be to allow them to become fully established before beginning to cut. Although I object to patching up very deficient beds or plantations, it is an advantage to fill up a blank when it only occurs here and there, and in that case planting is done in the same way as is recommended for the new plantation. Asparagus is much benefited by being mulched in summer, and as soon as it is seen where the young growths are, a quantity of short manure should be placed round each plant. The roots being near the surface they are apt to suffer from drought, which this mulching will counteract and benefit them to a great extent. I do not know of anything that injures Asparagus more in summer than wind. Let anyone look over a plantation after the shoots have attained a fair height, and they will observe that many of the shoots have been broken short off at the root. This not only hinders the shoot from developing further, but it also injures the crown for the succeeding crop. This must be avoided, and the best way of doing it is to put a stake to each plant and tie the stems so firmly to it that they cannot be blown about, upset, or broken off. I may further remark that Asparagus is very late this spring. Some years we have cut quantities of it by the second week in April, but this season we will not have a dish until May, as the heads are not yet visible. In cutting, at first, a number of the later stems may be destroyed if care is not taken with the knife, as those who push down and cut it as low as possible can easily cut over some of the young stems that are not visible above ground. I have no doubt there are many of your readers who desire to raise their own Asparagus roots, and it may interest them to know that it can be easily accomplished; 1 oz. of seed will produce hundreds of plants, and it rarely fails to germinate. It should be sown in drills 3 inches deep and 15 inches apart. We sow a little annually to keep up a supply of roots for winter forcing. The seed is sown thinly, as then plants can be easily disentangled when they come to be transplanted at the age of two or three years. A rich light soil is the best for the seedlings, and, apart from keeping them free from weeds, their cultural requirements after sowing are nothing worth speaking of. J. MUIR.

Margaux.

SEEDS.

ALL kinds of early seeds sown in the open ground have been severely tested during the past few weeks. Market growers, whose breadths of the Brassica family, Lettuce, Radishes, Wallflowers, and similar things are extensive, have felt more than usual alarm at the evident inactivity of the seeds, sown under comparatively good auspices, early in March, the ordinary time for such sowing. In not a few cases, that alarm has led to renewed sowings, whilst others have still faith in the germinating powers of seeds which have so long been buried. It is a good deal in the favour of the latter view that seeds last year were very good, and good new seed will endure much cold and wet. Old seeds find it hard to struggle into life even under the most favourable conditions, whilst during such a season as that we have been passing through, they would soon decay. Even Peas, such as Supreme and Harrison's Glory, second early, but usually hardy kinds, have done badly, and many have already decayed, so that it is doubtful whether the remainder will be worth leaving. These results are found in soil that is open, but fairly dry. The heavy snowfall which took

place recently, and which in thawing so terribly saturated the soil with coldness, doubtless was the chief cause of the mischief, but to that we have had superadded such a long continuance of cold nights and bitter north-easterly winds, that no encouragement has been given to germination, even of the hardiest things. It is just possible that, in some cases, coverings of straw or of dry litter have helped to keep the soil protected; but even such coverings exclude sun-heat, and that is the one thing needful for the rapid germination of seeds. There is a strong belief held that slow germination of seed means not only slow growth in the plant, but weakened constitution later. That is most probable. The same thing is found in animal life, and it is very likely to exist in the vegetable kingdom. No doubt it will be urged that to ensure rapid germination, and therefore healthy growth, sowings of all seeds in the open should be deferred till a later period of the year—very excellent advice, which may be acted upon by all who can foresee what the spring-time is to be, or where the exigencies of business put no pressure upon garden operations. But when it has been the rule for generations to sow hardy seed in March, when favourable opportunities offer, and usually with good results, it needs strong argument to show that a month's delay will be better. Earliness in all things grown for sale is of such importance, that much must be risked to ensure it. No doubt it would in the end pay market growers over and over did they furnish themselves with an abundance of cheap frame-lights, which they could, for purely temporary purposes, lay on a frame-work over beds of seeds which it is important should be early. Those who sowed Brussels Sprouts, for instance, early in March, in the open ground, will still find the seed lying dormant or making weak efforts to grow. Similar sowings made under glass would show plants an inch high, robust, and in great plenty. The same might be said of Lettuce and similar things; indeed, such are now the inclemencies of our spring seasons, that frame-lights, to afford protection to seeds as well as to concentrate sun-heat, are more than ever becoming essential in market culture. In our climate frame-lights need be idle only for a month or two in the autumn when cleaning and painting are needful. In other respects autumn sowings, spring sowings, Cucumbers, &c., seem to give to lights very ample employment. It is very probable that even in private gardens we shall hear of failures in early sowings where the soil is naturally cold. It will be well to give warning in time, that blame will hardly attach to the seeds. So many sown just in time to have burst their germ, or, as the current phrase is, to be "milky" just when the snow came, were utterly destroyed, but where the coating remained intact, no doubt those, if weakened, will still prove lively. It would be very unfair to place upon the seedsman's shoulders responsibility for losses through early sowings in a cold, ungenial season. Early planted Potatoes seem to be equally restful with seeds, but then tubers still in the store have remained far more restful than any previous season could show—pretty plain proof that the soil could not have promoted germination. Of course, it is a gain in all large gardens to get certain sowing and planting done early, because each week brings its own urgent labour. Potatoes buried more deeply have probably not suffered from the snow water, and have simply remained dormant. Seeds nearer the surface are more exposed to fluctuations of temperature, and, being so much more excitable, are in greater danger. A bad seed plant in spring offers to market growers a bad start for the year, but they still hope for better things when the winter has finally departed. A. D.

Mushrooms.—I send for your inspection two Mushrooms. I have some extensive beds made with some spawn from a well-known nursery, and these are the first produce. My family say they disagree with them. They look strong and coarse. Do you consider them a sound variety, and is the fault one of growth? Have they been staked in too cold and dry a bed as they come up in clusters? I

should be glad of an opinion in THE GARDEN before I take any action.—HERBERT G. BAINBRIDGE.

* * * The Mushrooms are perfectly good ones. A strong lens, however, shows them to be infested with very small transparent mites. A good many minute larvae are also in the two examples sent. Possibly there is something not quite right with the beds. W. G. S.

KITCHEN GARDEN NOTES.

BROCCOLI.—Referring to recent notes by several correspondents, I may mention that the varieties that have stood well here are Veitch's Model, Sutton's Safeguard, and Late Queen; other kinds, except Purple Sprouting, are destroyed; obviously, therefore, these kinds are worth looking after. But then it would be a mistake to grow only such kinds; in the first place, because we are not likely to have a frequent repetition of such severity; and, secondly, we should have a very late season, indeed, as all are late (April and May) kinds. We have just made a sowing of mid-season kinds, but mean to defer sowing the late kinds for another fortnight. Late sowing we prefer for two reasons: first, because the ground on which to plant is not available till the early Potato crop is harvested; consequently the plants would be likely to get stunted before they could be planted out; and, secondly, by early sowing and planting the plants get so abnormally large that the growth does not get hardened or ripened; and hence frost is the more destructive. We raise the plants on a shaded east or north border, and sow thinly in drills a foot apart, a mode that renders pricking out of plants unnecessary; sometimes, to prevent overcrowding, we find it desirable to thin out the seedlings. I ought to add that we select a cool shaded border for the seed-bed, because in no other way have we been able to escape the ravages of the Turnip fly.

CABBAGE. Continued north-easterly winds notwithstanding, our autumn-planted plot will soon be ready; All Heart and Dwarf Incomparable are the earliest. The seed was sown in the second week in August, and there is no premature seedling. We have spring-raised plants in sheltered turf pits ready for planting out as soon as these cold winds subside. No other sowing will be made till August, as Cabbages are not in much request when there is plenty of Peas, Beans, and Cauliflowers to be had.

SAVOY, COTTAGERS' AND SCOTCH KALE. We have made the general sowing in drills, the same as Broccoli. Dwarf Uln Savoy is the favoured variety, and by planting from the same seed-bed at three several times, at intervals of from ten days to a fortnight, a long succession is secured. In regard to Cottagers' Kale, such procedure is not requisite, as from one planting a supply of sprouts can be had the whole season. Next to Brussels Sprouts this is the most profitable green vegetable that can be grown, and not the least of its good qualities is its hardiness, for not more than 3 per cent. of the plants have succumbed to the severity of the last two winters. Scotch Kale, or Curled Borecole, is very inferior to the former, as the quality is not so good. It is nearly as hardy, but is very deficient by comparison in productiveness. The tall Curled is the only kind we grow, as the dwarf varieties are too unproductive, and do not make up that want by superior quality.

TURNIPS. Possibly the earliest sowing, or a great part of it, may run to seed; therefore, another sowing has just been made: Early Munich and Six Weeks are the kinds sown. Our ground is light and too dry for Turnips in the height of summer, and we have, therefore, to select the most shady and dampest positions; and the most suitable manures we have proved to be salt and wood ashes. The ashes we intermix with the soil when digging, but the salt we scatter over the soil after the seed is sown and covered in, and to the presence of these two manures I attribute our immunity from attacks of fly—I wish I could say also from the delinquencies of birds, just as the seeds are bursting through the soil. Against these we have to have recourse to netting.

HOING.—Better weather were impossible for

this description of work, and, therefore, we have gone over every crop and bit of ground that we thought might be benefited by the operation. Rhubarb, Cabbage, Onions, Broccoli, Broad Beans, Spinach, Lettuces, and the first planted Cauliflowers have all had their turn, and as soon as the seed-rows of the various spring-sown crops are visible, we shall hoe these also; having a strong predilection to kill weeds before they are visible, every bit of unoccupied ground has to undergo the like process.

GENERAL WORK. To protect Potatoes on south borders by earthing up, also to earth up Peas, and to stake those not yet done. Another sowing to make, as also to sow dwarf French Beans and Scarlet Runners, Lettuce, Cauliflower, and Brussels Sprouts to plant out soon as we get rain. Fill in drills of earliest planted Cauliflowers, sprinkle Asparagus plots with salt, and plant out the remainder of Seakale cuttings made from the last forced plants. W. W.

MARKET BASKETS.

PROBABLY the sieve or bushel basket of the London market is one of the heaviest and most cumbersome to be found anywhere. It is, however, quite a basket of convenience, and not to be regarded as either light or elegant. Round in form, with depth about three-fourths of its width, it is yet found a very fair measure, though hundreds of thousands be tested. That there is a tendency on the part of such baskets to enlarge somewhat with use there can be little doubt, because wicker-work, however strongly made, will somewhat loosen in time. On the other hand, the baskets wear out chiefly at the rims first, and what is gained in expansion is as soon lost in top reduction. But then it is said that the average life of a basket is about one year only. That is short enough, and by no means merry, for these wicker receptacles work very hard, and especially during the Potato season. Except when fresh from the maker at this time of the year, and when cover is of course found for them for a few weeks, they know nothing of care or of shelter. Pitched about as though of iron rather than of osier, exposed to all the winds and rains of heaven, very often loaded on to hot reeking manure, and perhaps so left all night, when the return journey from market has been a late one, clogged with dirt, saturated with moisture, or baked literally in the wind and sun during hot weather; such is the rough treatment to which market baskets are exposed. In removing them from a van no one thinks of employing care. The poor baskets are pitched over the sides as roughly as possible, the first one perhaps making a mark at which to throw all the rest. A labourer is perhaps displaying the density of his skull and the massiveness of his neck by carrying a lofty pile upon his head. It seems to be an effort at equitation, the which might evoke a cheer at a circus. When the baskets have been carried to their destination, however, down they go pell-mell, dislocating every rib and stay. What matters! They are only baskets, and there is plenty more making. The rough usage given in the winter when employed in the Potato fields is enhanced by the wet and dirt which abound and cling to them. Still further, it is not possible for these baskets to be used for the rough transmission of some 50 lbs. of Potatoes many times without suffering appreciably. No wonder, when all is considered, that the average life of a bushel basket is put at one year only. The white or clean osier baskets are the most enduring, but also the dearest; whilst the brown osier, that is the non-stripped rods, are the cheapest. They are less seasoned, and, still further, the bark is but the more retentive of wet. Prices range from 11s. to 21s. per dozen, according to quality and season of making. Thus I see orders are now being executed because there is less pressure now than will be the case in the summer, although the baskets can hardly be needed before Peas and new Potatoes are plentiful. Made with a stout rim and bottom slightly hollowed inwards, bushel baskets, however heavily loaded, may be built up to a great height, and if Peas alone, which reach perhaps about 10 lbs. per bushel, as

many as 180, or even more, have been loaded on to an ordinary market van. Really though so cumbersome, the value of the round sieve bushel lies in the facility with which it can be so loaded; indeed, it is the rule to build market vans so that the bottoms shall contain three baskets, whilst a width of four is loaded when the rails are reached. Peas, Beans, and similar vegetables travel very well in baskets of this sort, but Potatoes, especially those having tender skins, are roughly served; and as for Apples or Pears, it would be difficult to provide them with coarser means of transit. No wonder so much otherwise good fruit is spoiled ere it gets into the market, because it has to endure so rough an ordeal. Half sieves are chiefly made of dressed or stripped rods, and, of course, mainly employed for the transit of fruit; hence their usage is lighter and they endure longer. Although all these baskets are made with considerable accuracy as measures, yet the bulk of fruit sold through them is weighed, as also are Potatoes. Handiness and experience on the part of the maker enables him to fashion his baskets evenly by merely measuring the breadth of the base of each first, and then the depth of the sides. The baskets have no handles, but for soft fruits are sometimes lined neatly with blue paper, and another piece is tied right over the top. The rims are broad; hence handling is comparatively easy. In many other districts market bushels and half bushels are oval in shape and have handles at each end. This is a very useful form, but lacks the solidity of the London basket. Still further, it is not possible to load one on the other, as is done in the metropolitan area. There can be no doubt but that market growers suffer a great deal in reference to baskets from market losses, but it is still more certain that the ordinary rough usage to which they are subjected is productive of the greatest loss. It is hardly conceivable that in any other country similar carelessness would be evidenced. Even in the commonest things of life there is ample room for greater gentleness and careful consideration.

A. D.

TREES AND SHRUBS.

W. GOLDRING.

COULTER'S PINE.

(PINUS MACROCARPA.)

As regards the merits of this Californian Pine as an ornamental tree for this country, there exists some diversity of opinion. Some look upon it as one of the finest of all Pines, handsome in growth, and very distinct from most

Branch of Coulter's Pine (Pinus macrocarpa)

others. In places where it flourishes it is undeniably an extremely fine tree, but on thin, poor soils or in exposed localities it is a failure, and where it does not thrive it is one of the most wretched-looking trees among all the

Conifere. The fact is, *P. macrocarpa* is fastidious in its requirements, and refuses to thrive if the conditions of soil and aspect are not to its liking. A moderate amount of shelter is essential for it, especially from south-westerly winds, and the soil in which it seems to delight in most is a deep sandy loam. Under such conditions it is a rapid grower, and soon develops into a handsome tree. The peculiar characteristics of Coulter's Pine are the long leaves, 9 inches or more in length, of a pale glaucous green, and which hang in dense tufts from the tips of the branchlets. The branches are always wide apart, and the branchlets comparatively few and devoid of foliage, except at the tips, so that it always has a thin appearance, and one might recognise a specimen of it a long way off. It is much less conical in growth than the generality of Pines; indeed, it often develops a

quite 60 feet. One of the largest I have seen of this Pine is in the Knap Hill Nursery, which is a very noble specimen, having a girth of trunk of over 10 feet at breast high. It was planted about the year 1839, and though I have not measured it, it must be nearly, or quite, 60 feet in height. Other specimens in the country are of large size, but it is only those that were among the earliest planted and placed under suitable conditions that have made noble trees. The nearest relative to *P. macrocarpa* is *P. Sabiniana*, but the two species differ in habit of growth as well as in leaves and cones, and not being so hardy as Coulter's Pine, is not therefore so valuable an ornamental tree.

The Laurel and its management.—Few shrubs, and my words will be endorsed by more than one forester, are capable of being neglected to

Coulter's Pine (Pinus macrocarpa); cone, cone scale, and leaves (natural size).

spreading head as broad as that of a Stone Pine. The cones are remarkable, being very large, a foot or more in length and half as broad, and each scale about the middle of the cone is furnished with a strong incurved hook, while those at the apex and base are simply prolonged into a point.

This tree is included among the many Conifers introduced to this country about fifty years ago by the traveller, David Douglas, who sent seeds of it to the Horticultural Society of London. The tree is said to have been originally discovered by Dr. Coulter, who found it in the mountains of Santa Lucia, in California, near the sea, and at an elevation ranging from 3000 feet to 4000 feet. It grows intermixed with the Sugar Pine (*P. Lambertiana*), the lofty heads of which tower above all the rest of the forest trees. *P. macrocarpa* grows to a height of from 80 feet to 100 feet, but no trees in this country have yet reached that height, though some must be

such an extent as the common Laurel; and it frequently grieves me to see it in such a state, for, perhaps, no other plant, in certain positions, is less adapted for taking care of itself. As a screen for buildings and unsightly objects, for shelter, for effect, and as a fence, the Laurel is commonly in use; yet how often do we find it neglected until it attains to that most degrading of all appearances in the plant line—a bare stem with a tuft of foliage at the top. When a patch of this shrub is planted, very great care is necessary to keep it by annual or bi-annual trimmings low and shrubby and well furnished from the ground upwards, and this is, fortunately, readily enough managed by simply studying the plant's mode of growth, and by removing or shortening, as may be considered most suitable, all the longer growths, and which will induce a more bushy habit and stronger bottom growth. What is here said of the Laurel is equally applicable to the common Rhododendron—another shrub that when growing luxuriantly needs some one to look after it. It may be worth remarking that both of these plants, contrary to the usually expressed opinion,

will shoot out freely enough if cut over during the summer months. Necessity compelled us last summer to cut over a considerable number of both these shrubs; they were from 6 feet to 30 feet high at ground level, and a couple of feet therefrom. The work was performed under the impression that the stumps would no more send out fresh shoots and leaves; but not so; they are as green now as if they had been cut over at the usually prescribed time in early spring. I must confess that I was no little astonished at how freely the young shoots were sent out, but this is only another instance of what efforts Nature makes to preserve life. A. D. W.

Spiræa opulifolia aurea. The first half of the season sees this golden-leaved shrub at its best, and perhaps at no time is it more effective than just as the young leaves are partially expanded, for the opening buds give to the branches the appearance of being thickly studded with golden blossoms. The attractiveness of the shrub is also heightened by the fact that at this time many of its associates are still wearing their winter garb. It is a form of the well-known *Spiræa opulifolia*, but differs from that kind, besides the colour of the foliage, in being much less vigorous than the type. Another of the same tint equally bright in spring is the golden Mock Orange (*Philadelphus coronarius aureus*), which given a sunny spot will retain its colour throughout the summer. The depth of colouring in all of these golden-leaved shrubs will depend to a great extent upon their position, for if shaded in any way the hue of the foliage is not so rich as if fully exposed to the sun.—T.

Magnolia Halleana. This choice dwarf variety is now in fine flower against a south wall, and the pure white, sweetly-scented blossoms are greatly admired. One plant some 4 feet 6 inches in height is allowed to grow loosely, and every twig is literally studded with blossom buds yet to open. Being perfectly hardy the trade should get up a great stock of this plant, as it is sure to become a general favourite for forcing, cutting, and decorative purposes. *Pyrus Maulei* is a worthy dwarf wall companion to the above. Hardy as an Oak, it may be planted anywhere either for flowering and fruiting against walls or forming low hedges or clumps in the grounds. Indeed for this purpose I think it is best adapted, as it does not submit so kindly as other members of the genus to close and formal training. I have tried it in different ways and find the leave-alone system, after it has covered its allotted space, the best and most agreeable mode of dealing with it. It throws up numerous ground shoots or suckers, which no doubt might be taken off and converted into stock, but I prefer allowing them to ramble.—W. C.

Deutzia crenata fl.-pl. Though this *Deutzia* cannot be forced into bloom so early in the season as the smaller-growing *D. gracilis*, yet it will flower well under glass at this time of the year, and in the shape of good-sized bushes is very useful for greenhouse or conservatory decoration. When in the open ground the exterior of the blooms is of a pinkish tinge, but under glass this is not so pronounced. At the same time there is a variety (*candilissima*) in which the blooms are pure white, and on this account it will by many be preferred to the ordinary form. Apart from their adaptability for forcing, they are beautiful flowering shrubs for the open ground, and though by no means particular in their requirements, they are seen to the greatest advantage in fairly good soil, and so situated that the wood is thoroughly ripened and the plants do not suffer from drought. The close mass of fibrous roots common to all the *Deutzias* is greatly in their favour when required for forcing, as they can be carefully lifted in such a way that scarcely any check is inflicted upon the plant.—T.

SHORT NOTES.—TREES AND SHRUBS.

Trees for churchyard.—Will any of your readers kindly give the names of the trees most suitable for planting a disused churchyard in the centre of a seaport town on the north-west coast of England? Soil sandy; no interments have taken place during the past twenty-five years.—T. F. I.

Pyrus Maulei.—This is the most profuse-flowering *Pyrus* I have any experience of. Its numerous long shoots

are completely covered with the pale strawberry coloured blossoms in March and April, and as the flowers are distinct in colour and so very plentiful it becomes a very conspicuous object in flower borders or shrubberies. When the late Mr. Maule, of Bristol, to whom we are indebted for this unique *Pyrus*, first introduced the subject here he had a pot of jelly made from the fruit with him. This is a great recommendation to the plant, as the fruit, which it bears freely, makes a superb preserve. J. Muir.

GAULTHERIA SHALLON.

ONE would suppose that such a beautiful old evergreen trailing shrub as this is would be so well known and so commonly planted, that there would be no need to direct attention to its value. There is, in fact, no more valuable trailing shrub for clothing shady banks or even

Gaultheria Shallon.

exposed banks in damp places than this is, provided the soil is light. No one has ever questioned its hardiness, even in Scotland, where indeed it seems to be better known than in the south, for it has been largely planted there as an undergrowth in plantations as covert for game. An instance of this is at Balmoral. It is one of the few shrubs that will thrive in the dense shade of Fir and Pine plantations, even if the soil is very sandy. It is most at home in a damp, peaty soil. I saw an example of this in the Knap Hill Nursery the other day. The whole nursery is traversed by ditches, along which water runs the whole year, and in some parts the banks of the ditches are covered entirely with *Gaultheria*, and I have never seen banks more beautifully clothed. It is a capital shrub for planting among ugly tree stumps, with which some people persist in studding banks, and consider them beautiful; a strong growth of *Gaultheria* helps to hide the ugliness of the stumps, and with Ivy and other things, a

Gaultheria procumbens.

pleasing mass of greenery can be obtained. *Gaultheria Shallon* was introduced to this country just fifty years ago, so that it is now an old plant. It is a native of North America, especially on the Falls of Columbia, and generally near rivulets and lakes, and upon barren soils. When in luxuriant maturity it is 3 feet high, and when about a foot high bears an abundant crop of black berries, which are eaten by game, especially by partridges and pheasants; hence the value of the plant for covert. W. G.

Amygdalus nana.—Nobody who knows the dwarf Almond (*Amygdalus nana*) will contest the fact that it is one of the most beautiful of early

flowering shrubs. It forms a bush, which in March and April is covered with flowers, varying in colour from a pale pink to a deep red. Sometimes, but rarely, there springs from seed a variety bearing white flowers. Of this we have sown the stones, but they have always produced a plant with red flowers. Others may, however, have had a different result. In *Amygdalus nana* the colour is deeper than in any of the other sorts; but its chief merit consists in the long time in which it continues in flower. It is a healthy, strong shrub, with medium-sized deep red flowers. It is increased by means of seeds or suckers. The former should be sown during the same autumn they are gathered, and the young plants will appear the following spring; in the autumn, such plants as are strong enough can be put in their places. If this cannot be done before winter, it should be done in spring, before the plant commences to shoot up. Varieties which it may be desirable to keep ought to be multiplied by dividing the roots, by separating the suckers, or by means of root buds.—R. H.

Privet hedges.—I am almost grieved Mr. Muir does not know of any more satisfactory plant for hedges generally than Privet. One would have thought that a man living in our country would have seen a Holly hedge now and then, and if not, he certainly could use no plant less satisfactory for a hedge, either as a fence, or from an ornamental point of view, than Privet. It may have the merits of cheapness and quick growth, but there are other hedge plants cheap enough with which Privet cannot be compared for effectiveness. In the matter of quick growth, too, it would be better to choose a plant that grew slower and formed a good hedge than to "rush up" a hedge of Privet, and when it was made to prove useless, for Privet offers but poor resistance to cattle. Perhaps the most effective of all hedges is the Holly, which combines beauty with impregnability. A mixture of Holly and Quick makes a good hedge, or Quick can be used by itself. Then we have the Yew, Cherry, Plum, and the Hemlock Spruce, all of which make better hedges than Privet. Writing on the subject recalls to mind a pretty combination from an ornamental point of view which I saw a few days ago. It was a mixture of Quick and Ivy.—A. HERINGSTON.

Ivy on trees and buildings.—Few plants bear hard trimming-in better than the Ivy, and considering what a marked difference well-managed Ivy coverings present to such as are allowed to grow at will, the only strange fact is why we do not more frequently see this prettiest of all evergreen draperies attended to? One of the reasons is this, farmers on the whole, and cottagers as a rule, do not care a fig for plants nor their appearance. Too great exertion, but often ill-advanced, is required to make their ordinary crops profitable, and so gardening, whether in the soil or on the house-side, is neglected. Another reason is that farmers and cottagers, the former in the ratio of seven to one of the latter, lack the knowledge, and, combined with this, they frequently tell us that they lack the appliances necessary for attending to garden plants—their pruning and general treatment; but they always forget to tell us that they lack the inclination, and consider gardening in any form troublesome and expensive. This is no made-up story, for travel where you like, and pay attention to the matter as I have done, and you will ere long, if you cannot at present, fall in with my statement. The farmer is, perhaps, the worst floriculturist we have; his wife is usually considerably in advance, for she must have her window plants and bit of garden ground for flowers, but little, little is the assistance she gets either in preparing or planting the ground. In mining or quarrying districts we have flower-culture of no mean kind, and rare and curious are some of the plants I have met with in the gardens of such—showing that considerable interest is evinced in the collecting and culture of these by the owners of gardens in which they are found. But this is departing rather from our text. Neglected Ivy may in due season be made both ornamental and useful by trimming it hard and close to the building on which it is planted in early spring, and by mid-summer it will again be fresh and green, close and

compact, even of surface, better adapted for keeping out damp, and ten times more ornamental.—A. D. WEBSTER.

ROSE GARDEN.

T. W. GIRDLESTONE.

NEW ROSES AT CHESHUNT.

THE batch of new seedling Roses sent over from France during the last autumn, and now in course of distribution in this country, promise, as far as can be seen at present, to prove considerably more interesting than those of the previous year or two. Many of them have been, and are being, well flowered at Messrs. Paul and Son's "Old" Nurseries, Cheshunt, and though, of course, of the three or four dozen novelties annually imported all are not expected to take first rank: still the number of attractive varieties of probable permanent value is much greater than was discoverable last year. Although a gap is made by the fact that M. Lacharme makes no contribution this season, Lévêque swells the total with six seedlings, including Comte de Paris (fourth of the name!), a very fine, erect, deep crimson Hybrid Perpetual, on all hands admitted to be one of the best of the year and a very likely acquisition. Another of this set is unfortunately afflicted with a terribly long name, viz., Madame Edouard de Bonnières de Wierre, but has a good, bright, crimson flower, shaded darker, large, and of distinct form, being imbricated with a very full centre; petals large, and the characteristic form maintained even in the small side-blossoms. One of the most attractive Hybrid Perpetuals is Lévêque's Madame Bois, a Rose of the Victor Verdier race, but seemingly freer in growth and more perpetual; its flower is large and of most beautiful shade of pure rose colour, almost exactly the tint of Marquise de Castellane, but a trifle more salmony—an addition in a very desirable line of colour.

Another acquisition in this section (although classed as a Hybrid Tea, and said to be raised from Baroness Rothschild's Madame Falcot) is Guillot's Madame Joseph Desbois, a full, well-formed, nearly white Rose with a flesh tint, more in the way of Lady Mary Fitzwilliam than any other variety, but, as seen under glass, paler in colour.

The Tea scented varieties, as has been generally the case in recent years, form a strong contingent, and include varieties from some of the best known raisers. Luciole (Guillot), though larger and fuller than appears in the plate given in the current number of the *Journal des Roses*, hardly looks likely to make an exhibition Rose; but it is a charming addition to the bud Teas, in hue a delicious combination of clear rose, pale cream, and yellow, not unlike Camoens, like which variety also it makes an admirable forcing and pot Rose.

Madame Scipion Cochet (Bernaix) is a promising flower, full and of good size, having large white outer petals and yellow and apricot centre, something in the way of Madame Angèle Jacquier; and another seedling, M^{me}. Etienne, from the same raiser, is also very pretty, and has a white flower with a pointed, twisted centre before fully expanding, the outer petals being shaded and washed with rose. It is, however, impossible to see these shaded Teas in true character under glass early in the year. Madame de Watteville when forced is so different in appearance from the exquisitely tinted flowers developed out of doors, as to be hardly recognisable, and therefore it is not worth while to note further than that Madame Etienne's

form and size are such as will make it worth while to try her colour out of doors. There is no doubt, however, about the colour of Duchesse de Bragance (Dubrenil), which is a clear yellow, seemingly between Monsieur Furtado and Etoile de Lyon. Both these well-known varieties are first-rate when at their best, but the former is delicate in habit, and the latter some growers find difficult to open out of doors; so that a variety that combined their good qualities would be welcome, and Duchesse de Bragance is said to open as freely out of doors as under glass.

An interesting break in the perpetual-flowering hybrids of *R. polyantha* comes in Josephine Burland (Bernaix), a variety approaching more to the type of the Teas in flower, while retaining much of the multiflora character in foliage, &c. The flowers are white, of moderate size, solitary, erect, as perfect in form as Madame Bravy, and likely to be a popular bouquet flower. This variety seems an indication that the hope expressed of obtaining a race of hardy light Roses by means of *R. polyantha* is well grounded.

Of last season's novelties, Her Majesty was well to the fore, the magnificent form and finish of the bloom indicating the prospect of a rich harvest to the exhibitor during the coming campaign who may possess cut-back plants, which, by the way, should not be hard pruned. Several plants which had been severely cut back had produced a splendid, but flowerless growth. Lacharme's Hybrid Perpetual Clara Cochet also seems likely to take a permanent position as a greatly improved Catherine Soupert; and the same raiser's polyantha hybrid Max Singer, in this case a climber and not perpetual, promises to be a real addition to climbing red Roses, of which there are at present so few. The seedling resulted from a cross between *R. polyantha* and General Jacqueminot, and produces an abundance of bright red, very well formed flowers.

Of the new Hungarian climbing Roses, which are the outcome of M. Geschwind's endeavours to raise a race of Roses that shall be proof against all frosts, Erinnerung an Brod has deep red flowers which are deliciously fragrant, and may be useful.

The Cheshunt collection of Rose species and variations is now very extensive and interesting, and among those charming forms that have been flowering freely under glass are the Gistulike *R. berberifolia* Hardy, with its single yellow flower and purple centre; *R. clinophylla* plena, bluish white; Veitch's pretty Rose Britton (*lucida* fl.-pl.), in its rosy clusters; Paul's Single Perpetual White, very pure and free, and many others. The success that has already attended the employment of *R. polyantha* as a seed parent in Rose-raising will, it may be hoped, induce hybridisers to persevere in experimenting with these valuable seed-bearing species, so many of which possess attractive and valuable qualities that might well be introduced among our highly-bred and, in many cases, weakly-constituted garden varieties.

Sweet Brier.—"Cambrian" (page 331) while praising the Sweet Brier says, "it is hardly an attractive plant." It would be difficult to name a plant which is more attractive, apart altogether from its scent. Few people treat it fairly, so as to allow of its development into the vigorous and graceful bush which it naturally is. When they do, they are rewarded by a free and handsome bloom in summer, and in autumn with a brilliant show of brightly coloured fruits. These good qualities will not be obtained if it is grown in the form of a hedge. Surely nothing in our gardens is more deserving of attention.—A. HERINGTON.

HYBRID ROSES IN POTS AFTER BLOOMING.

THESE may be stood in a cool house facing north, and it will be better if no heat at all is used. They must be watered when they require it, and fumigated when green fly shows itself, and in April, or as soon as very severe weather is over, they can be examined and, where necessary, re-potted; then place them out of doors for the summer. A 12-inch pot is a most unwieldy size to grow a hybrid in, and unless the plant is extraordinarily large there is no possible need of it; a 10-inch pot is as large as they need when four or five years old.

The treatment with which I have succeeded best for several years has been to place the plants as soon as the blooming is over—generally my first plants are ready at the new year—in a north house about 6 feet wide with a good bed of ashes on the floor; on this I stand the plants as thick as the foliage will allow, water as soon as put in, and continue watering when necessary. Here they stand without a particle of sun or fire-heat till about the end of March, when the sun will begin to warm the house a little during the middle of the day. During all this time, except during very severe weather (when I frequently got 12° to 15° of frost in the house, yet it does no harm), they will keep steadily growing, and by April 1 the new growth is generally 2 feet long. I now give plenty of air every day in mild weather, and by the end of the month or the first week in May I turn them all out-doors into their summer quarters and grow them on in the usual way till August.

Anyone having surplus plants of any good varieties that have been forced during early winter and treated in this way, by planting them out in the open ground during mild weather in April or early in May, can have a fine crop of flowers eight or ten days earlier than from the plants which have been out all winter. The cool-house treatment gives the plants a partial rest (though if treated right they never lose a leaf), which never fails with me to produce a fine crop of flowers, as above described. Of course, if the plants are grown on in pots for the next winter's work, it is best to pick this crop of buds off before they begin to open. The most important thing to guard against is allowing a severe snap to catch the plants dry; should such occur, the plants suffer severely.—J. N. M., in *American Florist*.

ROSES THE BENNETT AND AMERICAN BEAUTY.

MY experience with the Bennett has not been quite satisfactory. I admire its style of bud, its colour, and the manner in which it will retain its colour, even under circumstances injurious to the colour of some other varieties, such as Pierre Guillot, but I have found it so prone to black spot and red spider that I have lost much of my original esteem for it. Liberal applications of cold water will, of course, keep the spider in check, but I have yet to learn of an effective remedy for black spot. A European scientist recommends hand-picking and the immediate burning of the leaves, but this is a remedy I have not yet found time to test. A year or two ago, by way of experiment, I potted up a couple of Bennetts, using the usual compost for one, but adding a little sulphur and lime to the soil for the other; they remained side by side for about three months, the doctored plant showing little sign of spot, although the other was constantly frescoed; they were subsequently planted on the benches with other Bennetts. I tried the lime and sulphur in planting, and for months afterwards I applied it in various forms, also using every other remedy coming under my notice, but I signally failed to reduce my crop of spot.

As to the Beauty, well I am perfectly in love with her. I think she is "just too sweet," and remarkably free from the many ills to which Roses are heir. I am little troubled with mildew, spot, or spider, and the Beauty appears to carry less blind wood than any other variety I know of. Late last autumn I planted a few very small plants on the benches; they have not made any 8-foot or 10-foot canes in the meantime, few shoots now being over a foot long, yet I have cut some very fair buds, one

bloom which I cut lately being 1 inches in diameter; with me it seems to do best in a good, stiff soil, and fed very sparingly, if at all. I give a little liquid manure about the time the buds are developing, but with this exception I feed it less than any Rose I ever handled; I find also that it enjoys a comparatively cool atmosphere. I am raising a few young plants which I intend to force as Hybrid Perpetuals next season, but grown in the usual way; and with proper care and attention I can see no reason, judging from my own experience, why American Beauty should not prove a profitable Rose to the commercial grower. "There is nothing succeeds like success," and the grower who succeeds in taking out of American Beauty all that is in it will not need to bother much with the Bennett. — A. W. M., in *American Florist*.

Marechal Niel Roses In Mr. Muir's note in your columns (p. 356) I read him to say, Easter, 1886, he had dozens of Roses, but Easter, 1887, was a miss. My Marechal Niels have done well even in 1887. From Monday, 11th instant, to Monday, 18th, I have cut eighty-two dozen of very fine flowers. I have never seen them so beautifully coloured—a deep golden yellow, and what makes them, in my eye, doubly valuable, the foliage is perfectly clear of mildew. If a good colour and a green foliage is wished for, keep the pipes warm, and give air sparingly. Cold blasts bring mildew and a close atmosphere assists, but warm air is the thing to aim at. R. GILBERT.

GARDEN DESTROYERS.

CROP-DESTROYING INSECTS.

THE tenth annual report on "Injurious Insects" has just been published by Miss Ormerod. Like its predecessors, it contains the result of observations made the previous year by a number of persons in various parts of the country; consequently a large amount of very valuable information has been got together. The number of different insects reported on is not quite so great as last year, when observations on twenty-nine different species were recorded. In the present report nineteen different insects are dealt with, and of these eight have not previously found a place in these reports. Foremost among the eight stands the Hessian fly, about whose arrival at one time there was so much doubt. What was at one time considered only a scare, like that about the Colorado beetle, has unfortunately only proved to be too true, and, as Miss Ormerod truly says in her preface, "1886 will be always notable agriculturally as the year of the first appearance of the Hessian fly (*Cecidomyia destructor*) in Great Britain as a destructive corn pest." Where it has come from remains still to be made out; but we see from our own observations of the last few months that there are means of prevention of the multiplication of this pest easily available in this country by which we might reasonably expect to keep it in moderate bounds if these measures are used. If they are not, the example of its rapid spread over about two-thirds of European Russia—so that since its first observation in that country in 1879 it has become the most destructive crop-scourge of the land—shows what we have to fear.

It would appear that the Hessian fly was first known as a destructive insect in America about 100 years ago. It was given this name because it was supposed to have been introduced (according to Kollar) in straw with the Hessian troops during the American war. There was, however, no grounds for the supposition; but it now unfortunately exists, and causes an enormous amount of injury, in France, Austria, Hungary, and Southern Russia. Last year it appeared in this country in Hertfordshire, Bedfordshire, Essex, Inverness-shire, and Perthshire. As regards the appearance of an infested plant, Miss Ormerod says: "On examination in the fields near Hertford on the 30th of July I found the stems doubled sharply down a little above the joint (the second one from the root), and between this double and the joint below there lay, closely pressed to the stem and covered by the

sheathing leaf, the flax-seed-like chrysalis cases. The injury is caused by the fly maggots lying at the same spot sucking the juices from the stem, which is thus weakened; presently, although both the stem and ear above are more or less stunted, yet the weakened piece of stem cannot bear their weight, and it bends sharply down at the injured part; sometimes a gall or some amount of swelling of the stem occurs just above where the maggot fed, but in the specimens I examined this was rarely noticeable."

It does not appear how or from whence this pest has been introduced, but it seems possible for it to be transmitted unwittingly from one country to another in straw or corn that has not been thoroughly cleaned. When a root is attacked, there is no means known of relieving the plants from this insect; so that preventive measures are what farmers should rely on for protection against it. The chief of these appears to be not to sow Wheat until the autumn brood of flies is dead; this usually takes place in America in the middle of September. The United States Entomological Commission recommended that Wheat should not be sown before September 20.

The corn sawfly is an insect which injures corn crops much in the same way as the Hessian fly to an ordinary observer, but the straw is injured at the ground-level, and the maggot is within the stem; the stem does not bend, but breaks off short at the injured part. It is not in sufficient abundance to be a very destructive pest. Last season earwigs were a great nuisance in many places, and in some localities from this report they appear to have caused much injury to Cabbages, Turnips, Mangold, and Kohl-rabi. They also attacked the Tobacco crop, which was a new crop last year in this country. A very graphic account of the plague of earwigs is extracted from the *Field*, the writer of which gives an account of various articles of food into which they crept. Eggs, however, are not mentioned. A correspondent wrote to me during the summer recommending fowls as being great enemies to earwigs, and adducing as a proof that on opening his egg that morning at breakfast he had found two earwigs (dead) in it. I was sorry not to be able to accept this proof, and suggested that probably the eggs had been cracked and the earwigs had crawled in. Various methods are suggested for destroying these insects when they are very abundant. Clover weevils are reported on for the first time. These little beetles feed on the leaves of the Clover, and lay their eggs in the flower-heads; their little grubs make their way to the seeds, on which they feed. Though this insect has not been alluded to in these reports before, it is an old and well-known foe to Clover, and has been described, figured, &c., in Curtis's "Farm Insects," a book published many years ago. Another disease which has not hitherto been mentioned in these reports is Tulip root in Oats. When Oats are attacked by this disease, the base of the stem becomes swollen into a kind of bulb, round which grow a number of distorted roots. The authors of this disease are eel-worms, very small creatures, which are not insects, but are worms belonging to the Order Nematoda. These eel-worms are very long-lived, and will recover even after having been dried for some considerable time. Deep ploughing is recommended as one of the best remedies, so that the eel-worms may be buried as deep as possible. If this precaution is taken after an infested crop has been removed, and the next crop is one which this pest will not attack, the soil ought to be in due time quite free from them. The well-known disease, Wheat-ear cockles, is caused by a very similar worm. This disease is also reported on. It appears to be very easy to prevent Wheat being attacked by taking care not to sow infested seed. This can be ensured by putting the seed into water and stirring it about; the cockles will rise to the surface and float, and should be removed.

The Wheat bulb fly (*Hylemia coarctata*) is another insect which makes its *debut* in the report this year; as yet it does not seem a very troublesome pest. Under the heading of long-horned centipedes a figure is given of the long-horned centipede (*Geophilus longicornis*). This creature is probably partly

carnivorous and partly vegetarian in its diet. As a vegetable-eater it probably does more or less harm to corn crops. I say probably, as the case against it is by no means proved; but in the same figure the common centipede (*Lithobius forficatus*) is depicted. This creature is generally admitted to be entirely carnivorous, and should be protected in every way; it is therefore a mistake to figure it with the other without mentioning that it is a beneficial and not injurious creature.

Eighteen pages of this report are devoted to beetles which attack the Mustard crop. Of these there are four kinds, two of which attack the leaves and the others the flowers and seeds. The Mustard beetle (*Phadon betulae*) attacks Mustard much in the same way as the Turnip-leaf beetles injure Turnips, and they are joined in their ravages by the latter beetles, which appear to destroy Mustard as eagerly as they do Turnip crops. The various observers of these insects seem to agree in the advisability of sowing Mustard as early as possible, so that the plants may get a good start before the beetles attack them. Dusting the plants while the dew is on them with certain mixtures which are given is recommended. The beetles which attack the flowers of the Mustard are very small (not more than 1-12th of an inch in length), and of a dark metallic green. They lay their eggs within the buds, and the grubs hatched from these eggs feed at the base of the blossoms. There appears to be no remedy when a whole field has to be dealt with. The fourth kind of Mustard beetle is the Turnip-seed weevil, which does not seem to be a very injurious insect, but its grubs have been found feeding on the seeds. Growing Mustard as a preparation for wheat has been generally considered as a sure means of preventing the latter crop being attacked by wireworms, as these insects are supposed to have a great dislike to Mustard; but two of Miss Ormerod's correspondents write, saying they find Mustard is attacked by wireworms.

In reporting on the Turnip gall weevil, Miss Ormerod says: "Partridges are said to be very fond of the maggots, and to frequent Turnip fields for the purpose of pecking them with their beaks out of the galls, but as one great part of the damage of the attack consists in the escape of the maggot, causing holes by which wet and injurious insects make their way into the Turnip, the still larger openings down into the gall cavity caused by the birds' beaks are a doubtful benefit." Though the individual roots may not be improved by the partridges extracting the grubs, it should always be remembered that in killing the latter the partridges are of great service in reducing the number of the next season's beetles. Horse warbles are reported on for the first time this year. The attack does not seem to have been severe anywhere, but it has been noticed in about a dozen different localities in various parts of England. Horses are so much better cared for as a rule than cattle, that they are not likely to suffer so much from these pests. The scientific name of the fly does not seem to have been accurately determined by Miss Ormerod.

In these reports the insects are classed under the name of the crop they attack. This I consider a very unscientific and undesirable plan. However, on this point there is much difference of opinion, but under the heading of "Corn" surely those insects which are nearly allied to one another should be placed together. Miss Ormerod, however, gives them in the following sequence: a fly, a sawfly, a beetle, eel-worms (which are not insects at all), and then another fly. With a little careful editing the report might have been considerably condensed, which would have been an advantage if the price was also reduced; 1s. 6d. for 109 pages is a high price, and more than many farmers would care to give. G. S. S.

Grubs on lawn. A friend of ours sends us a sample of pests with which his garden is infested to such a degree that nothing will live. He says his lawn is filled with them, as also his borders, and as soon as anything is planted it is killed by them. They literally swarm about an inch under the surface of the soil. We should esteem it a great favour

if you could suggest any way of getting rid of them.—OAKLEY AND WATLING.

* * In reply to the above, the grubs you forwarded are the grubs of the common daddy-long-legs (*Tipula cloracea*), or some nearly allied species, but they were so dried up and shrivelled that I cannot say anything more definite. Follow the ground as much as possible, keeping the surface well stirred, so as to give the birds a chance of getting at the grubs, or give a good dressing of gas lime; watering the Grass with 1 oz. of corrosive sublimate dissolved in a little warm water, and then added to forty gallons of water, might do good.—G. S. S.

FERNS.

W. H. GOWER.

ASPENIUMS FOR BASKETS.

THIS genus contains many well-defined species and an equal number of intermediate forms. They are widely distributed over all parts of the globe, and vary in size, from dwarf kinds only an inch in height to large graceful species with fronds several feet in length. *Aspleniums*, for the most part, are plants of robust constitution. This, combined with their diversity in size, renders some of the kinds suitable for any position in a fernery in which it may be desirable to place them. The kinds enumerated below are specially adapted for cultivation in hanging baskets, and display their charms to the best advantage when grown in this manner. Whatever the basket may be manufactured of, elegance of outline is the only thing necessary to take into consideration, as all other details will be hidden when the plants become properly developed. The interstices, however, should not be over-large, otherwise the soil is apt to wash through. In preparing the baskets for the reception of the plants, a thick layer of Sphagnum Moss should be placed all round the sides, as this will prevent the escape of the soil. The mould may consist of rough peat, loam, leaf-mould, and sand in about equal proportions, to which some tolerable sized pieces of charcoal should be added, as they will serve for drainage without adding materially to the weight—a point always to be studied when they are suspended from the roof of plant houses. Ferns in baskets are very liable to suffer from neglect, and frequently lose many fronds through drought. To avoid this the baskets should be taken down every morning through the summer, and be either dipped in a tank of water or the soil should be well soaked through with water from a rose-can, when, after draining, they may be replaced in their several positions. *A. longissimum*, the subject of our illustration, has few equals for basket purposes, the long pendent fronds being vivid green on the upper side, copiously fertile beneath, and prolific at the points. It is found in the Mauritius, in Malacca, and in Java, and requires a warm house to develop its beauties. *A. flaccidum* is a plant of a somewhat more spreading habit, with stout, bright green, thrice-divided fronds, bearing numerous young plants upon the upper surface, which add materially to its effectiveness. It thrives best in a cool house, and is a native of New Zealand. *A. rhizophorum* is an elegant species from Brazil and the West Indies, and requires to be grown in the warm house; the fronds are some 2 feet in length and very finely divided, the segments being vivid green. It is prolific at the extreme points of the fronds; these ends should be pegged into the sides of the baskets until the young plants it develops become rooted, when the connection may be severed; this practice will produce a mass of great beauty. *A. bulbiferum* is a free, massive-fronded species,

deep green above, where young plants are freely produced from little bulbils, by which it may be readily increased. It comes from New Zealand, and is one of the most effective large-growing kinds for a cool house. *A. appendiculatum*, from the same country, is a near ally of *bulbiferum*. Its fronds, however, do not taper so much to a point, but are more uniform in width throughout their entire length, less finely divided, and not so prolific. On the under side, the fronds are densely covered with dark brown sori. *A. caudatum* produces fronds some 2 feet or 3 feet long, once-divided, the segments or pinne being deep green and taper to a long point. It is from the East Indies, and requires

Asplenium longissimum.

a warm house. *A. flabellifolium*, from New Holland, is a very slender, small-growing plant, which requires a very small basket; it may even be used for suspending in a Wardian case; when robust the slender fronds are from 12 inches to 18 inches long, prolific at the points; the small pinne are fan-shaped and bright green. *A. fureatum* is a variable plant, robust in habit and spreading, fronds some 2 feet to 3 feet long with scaly stems; they are much divided, with deep green erose segments, and are very effective. It is found in various parts of Tropical America, and also in Madeira; that from the former requires a warm house, while the Madeira form thrives well in a cool structure.

A. laserpitiifolium is a bold, handsome, warm-house form from the East Indies, with spreading fronds some 3 feet or more long, ovate-lanceolate in outline, and three-times divided, the segments being small, cuneate, and vivid green.

The Killarney Fern as a town plant.—I remember Mr. John Adair once saying that if he could have but one plant for city culture, and could select that one, it would be the Killarney Fern (*Trichomanes radicans*), and he went on to say that "but few years have passed since the culture of this beautiful Fern baffled the skill of experienced gardeners." Loddiges often tried to grow it, and always failed; and Baron Fischer, superintendent of the Czar's botanical establishments, seeing it with the late Dr. Ward, flourishing in one of his Wardian cases, took off his hat, and made to the plant a low bow, saying: "You have been my master all the days of my life." It was therefore in a Wardian case Mr. Adair would grow this plant in the city of Dublin. One reason why he would praise it as a city plant is that it will grow as well in the garret as in the drawing-room, in the stable loft or darkest corner of a yard in any part of the city. But Mr. Adair grew it in his parlour in Merriion Square, and he has set forth how he managed it—not allowing it to have the sun upon it for seven years.

If what the plant has to grow in has a wooden bottom, line it with zinc, and have a hole or holes for drainage. Place pieces of broken potsherds with the hollow side downwards over the holes, and over all the bottom of the vessel. On this spread lumps of charcoal of 2 inches or 3 inches or more in diameter, or a layer of sliced Cocoa-nut rind, and upon this a layer of pieces of turf of the same size as recommended for charcoal. Sprinkle fine, peaty soil over these, and having laid down your plant, and sprinkled a little more of the soil over the rhizomes, water well with a fine rose. The atmosphere should be always moist, but these plants like some air, which much contributes to their fruiting, as this does to their interest and beauty.

Have any of the readers of THE GARDEN similar experience? In all the experiments of this character which Mr. Adair undertook, he brought to bear upon them great enthusiasm and undeviating attention, and he succeeded with many subjects to a remarkable degree.—R. D.

Adiantum aneitense.—This is a plant of somewhat recent introduction, and whatever aspect it may wear in a dried state, it may, when seen growing, be readily recognised from any other kind. It is an evergreen species, and although of a rigid texture, it requires stove heat, as it comes from the lowlands of the island of Aneitum. It has a creeping rootstock, and produces fronds from 1 foot to 2 feet long, three or four times divided and deltoid in shape; the segments are deep green, smooth on the upper side, and slightly glaucous beneath. We recently saw handsome specimens of this species in the Fern collection at Beddington House, Surrey.—G.

Pteris serrulata Mayi.—This is a most elegant form of the well-known old Chinese Fern, which is such a general favourite for room decoration and for Wardian cases in the house, whilst the numerous crested and tasseled varieties into which it has sported under cultivation are extremely ornamental in the fernery and for hanging baskets. The present sport is more compact than the type, all the segments being variegated with silvery white, and their tips divided into a flat triangular crest. This plant is rapidly becoming popular, and is largely grown by its raiser, Mr. H. May, in his nursery at Echnontou.—G.

SHORT NOTE.—FERNS.

Large Ferns (*P. Mr Donald, Edinburgh*).—The large Ferns you mention as having seen last summer in the Colonial Exhibition were specimens of *Todea africana*. It is also known by the names of *T. Barbara*, *T. australasica*, and *T. rivularis*. The examples of this Fern sent from Victoria to Kensington were very fine specimens, varying from 1 ton to 2 tons in weight.—G.

Doryopteris ludens (*T. J.*)—The specimens you send are those of the above species. We are glad to hear you have spores germinating, as we are not aware that it is in cultivation. The fronds are of two forms, the infertile ones being triangular, sometimes approaching hastate, supported upon chony-black foot-stalks, whilst the fertile ones are pedate, much resembling those of *D. pedata*. We should think it

will thrive in a cool fernery, as it is found in India at upwards of 1000 feet elevation, but yours from the Philippine Islands may be from a lower altitude.—Ed.

ORCHIDS.

W. H. GOWER.

ORCHIDS IN FLOWER AT CAMBERWELL.

THE condition of the extensive collection of these plants at Cambridge Lodge, the residence of Mr. R. J. Measures, thoroughly proves the possibility of growing Orchids in London, and teaches a lesson in their management worth recording. At the above place the cool system is carried out, even with the East Indian distichous-leaved kinds, such as *Vandas*, *Aerides*, and *Saccobolabiums*, to a greater extent than we have hitherto seen. In the house devoted to these plants the thermometer has been allowed to fall as low as 50° during the past winter, and the plants are now in the rudest health, their rich deep green leaves clothing the stems to the base. There are about a hundred spikes of bloom now pushing up on the *Vandas* alone, principally on *V. suavis*, *V. tricolor*, and its varieties. The rare and little-known *Vanda Gowerae* (undulata) here also finds a congenial home. This species, which in habit somewhat resembles *Camarotis purpurea*, but is more robust, produces an erect-branching spike bearing numerous flowers, which may be likened to miniature blooms of *Ceologyne cristata*, with the sepals and petals beautifully undulated. It has been imported from Upper Assam in great quantities, but has rapidly succumbed to the hot treatment it has received. The rare *Aerides rubrum* is also here thriving under cool treatment, bearing two erect spikes of bloom. About twenty-five years ago quantities of this plant were imported, but rapidly dwindled away through being placed in too high a temperature. We have always strongly advocated cool treatment for Orchids, but we were not prepared to see a grand example of *Renanthera Lowii* thriving under quite so low a temperature, as is here demonstrated that it enjoys. Beside the kinds enumerated the collection includes fine specimens of the Fox-brush *Aerides* (*A. Fieldingii*), *A. Schroederi*, *A. Lawrencei*, *A. crassifolium*, *Vanda Cathcarti*, *V. Sanderiana*, and many others of this section, every one of which appears to be in robust health. The lovers of this class of Orchids, therefore, need no longer object to their cultivation upon the plea that they require so great a heat that they cannot be enjoyed.

Cymbidiums also show how much they enjoy cool treatment. Gigantic plants of *C. Lowianum* are now in great beauty, bearing numerous spikes, on which are twenty and twenty-seven blooms, whilst numerous plants of *C. eburneum*, with their large ivory-white flowers, are very conspicuous. *Masdevallias* are very numerous, and now, in the middle of April, fire-heat is entirely withheld, whilst during the winter just sufficient heat is given to keep the frost out and the houses comfortable. Had this treatment been recognised earlier, the splendid consignments of that enthusiastic collector, M. Warszewicz, would have been preserved to our gardens, and our knowledge of Orchids some few years in advance of what it is at the present time. The houses devoted to *Cattleyas* and *Lælias* are slightly warmer than those in which the mountain Orchids from South America are kept. The specimens are numerous, but as those of the Triane section are nearly over there is not much bloom. A fine example of *C. intermedia*, however, bearing some thirty flowers, and others promise to keep up the succession until *C. Lawrencei*, *C. Mendeli*, *Lælia purpurata*,

and others commence. Amongst this family there is a remarkable instance of cool treatment being successful in *Lælia harpophylla*. Numerous plants of these have been subjected to the coolest treatment, even to the extent of several degrees below the freezing point, with the result that the growths are finer than those made in heat, but the flowers are only now at this date pushing up. In a house with about the same temperature as the *Cattleyas* we noted several fine examples of the chaste *Trichopilia suavis*, some bearing upwards of a hundred flowers, and also finely-bloomed plants of the pure white form *alba*; these were associated with such as *Miltonias*. Particularly notable were numerous specimens of *M. vexillaria*. These plants are subjected to a sprinkling of water from the syringe morning and evening, their rude health and the numerous spikes of bloom just appearing amply proving that this system of overhead watering is thoroughly congenial. *Cypripediums* are grown warm for the most part, and in this collection nearly every recognised form is represented, including several unique kinds. At the time of our visit a splendid new unnamed kind was flowering, which had been introduced from Tropical Asia. The flowers are as large and as deeply coloured in the petals and pouch as those of the finest varieties of *C. Harrisianum*, whilst the dorsal sepal is large and much brighter coloured than those of *C. cernanum superbum*. It is certainly a great acquisition to this numerous and popular genus. *Phalenopsis* are also grown largely, and although there is some improvement in them since our previous visit, we opine they would be further improved if their roots were freely exposed to the air. The *Dendrobiums* appear to be kept the hottest, and the house is gay with many hundreds of blooms of such kinds as *D. Wardianum*, *D. crassinode*, *D. Fytchianum*, numerous forms of *D. nobile*—amongst them a variety with white sepals and petals, which affords a pleasing contrast to the blooms of the dark-coloured forms. A very notable variety of *D. Brymerianum* is also blooming, its dark orange-yellow flowers being adorned with a much deeper fringe than we have hitherto observed in this species. All the *Dendrobies* are in vigorous health, and although now growing in strong heat, they have been subjected to a long period of rest in a cool house. In the houses devoted to the mountain plants from South America, the fine examples are numerous, and in some instances unique. These we will refer to upon a future occasion. One plant, however, *Oncidium concolor*, is noteworthy—a native of the Organ Mountains in Brazil. Here under very cool treatment, and suspended close to the glass, it is flourishing most vigorously, making pseudo-bulbs twice as large as its imported growths, and flowering most profusely. All and any of these plants are used without the slightest hesitation for indoor decoration at all seasons, and with no evil results. We therefore urge upon the largely increasing numbers of Orchid growers the advisability of adopting cool treatment, as it reduces the bill for fuel, increases the vigour of the plants, and consequently adds materially to the enjoyment.

Calanthes at Holloway.—The glories of *C. Veitchii*, *rubro-oculata*, and *luteo-oculata* have now passed away, but there are several newly-introduced *Calanthes* which are just now in great beauty in Mr. Williams' nursery at Holloway. The best of all is *C. Williamsi*. The pseudo-bulbs somewhat resemble those of *Limatodes rosea*, and the flowers are both large and numerous; the sepals and petals are white tinged with pink, whilst the lip is rosy crimson, very intense towards the base. *C. Regnierii* is another desirable, late-flowering kind with white sepals and petals, and a lip which varies in colour

from rosy pink to rosy purple. *C. Stevensi* resembles the last-named kind, but has less colour in the lip. We believe they all come from Cochinchina, and their period of flowering makes them desirable acquisitions. G.

Cattleya intermedia Laingi.—Although this species has been cultivated in our gardens for many years, there has been very little variation from the typical form. A variety now flowering with Mr. Laing at Forest Hill bids fair to bring this somewhat despised plant into the front rank. It is exactly like the type in growth; the flowers, however, are much larger, whilst the broad, flat, middle lobe of the lip is of an intense deep crimson-purple. —G.

Dendrobiums at Forest Hill.—The collection of these plants in Mr. Laing's nurseries is now very extensive. So great is the demand for Orchids that considerable more space in the nursery is required for their accommodation. Particularly fine are the hundreds of *D. Wardianum*, *D. crassinode*, *D. Fytchianum*, *D. Ainsworthii*, and various others. In growing these plants we observed that Mr. Laing favours small pots, and uses fibrous peat from which all the fine particles have been shaken away. This is pressed down very firm, and thus the roots have something to cling to, and the moisture runs quickly through. By this system the roots do not become saturated and soddened with loose, stagnant material, a condition so thoroughly inimical to the well-being of Orchids. G.

NOTES OF THE WEEK.

Editor's Table.—After a lapse of several years we propose to open this column for the present season of flowers. Interesting hardy and beautiful flowers of all kinds will be welcomed.

Irish Anemones.—We have received a beautiful gathering of the "St. Brigid" strain of Anemones, both single and double forms. The flowers are of great size, and very varied in colour, and when grown in masses must have a grand effect.

The Frost Report.—We are asked to state that the authors of the reports furnished for the compilation of the "Frost Report" may have a copy of the work free of charge, as well as the Fellows, on application to the Secretary of the Society. The report may be purchased, price 5s., from Messrs. Macmillan & Co., 29, Bedford Street, Covent Garden.

The Tamarisk. All the way from Stomoway (Lews Castle) comes one of the most graceful and curious things we have ever seen. It is a branch of the Tamarisk wreathed with flowers, and drooping shoots 5 feet long, so beautiful and so finely cut in every way, that nothing we can think of cut or engraving would give the least notion of it. It is grown in the conservatory at Lews Castle, and the warmth no doubt has produced such good blooms. Even where the plants survive in Western Europe we find the temperature is not sufficient to develop the lovely flowering qualities that this shows.

Camellia Mathotiana. I send you one of a dozen blooms I have cut on a *Camellia* on an outside south wall here. I think it is very good, considering that we have had sharp frosts every night during the past week. I see correspondents have been writing lately respecting the hardness of *Ficus repens*. I put a plant of it on the south front wall of a lean-to house last autumn and it is all right, only waiting for warm weather to commence growing again.—GEORGE FELLOWS.

* * * A very fine, fully developed bloom of *Camellia Mathotiana*. *Camellias* are not so tender as is generally supposed. We know of several plants that have been planted for many years facing due north, and they are in rude health and bloom freely every season.—Ed.

An American engraver. There is an engraver named Blane living in Philadelphia, in the United States, who has copied without permission or acknowledgment a good many of our beautiful cuts. In the present state of the copyright law between England and the United States this gentleman is perhaps within his legal rights; but putting his own name on the blocks which he copies without leave or acknowledgment compels us to publish the fact. He copies them by some photographic or other mechanical process, and then puts his own name

on cuts with the design or engraving of which he has had nothing to do. A member of an English artistic fraternity, known as the "horse-coper," when he steals a horse, does not flaunt the thing in people's faces, but with becoming modesty sometimes *paints* the animal another colour! Mr. Blanc does not hide his doings, but takes a pretty little cut of the foliage of the Teale (Dipsacus), drawn by Alfred Parsons and engraved by Huyot; takes off Huyot's name and puts his own name instead. He offers a large selection of engravings to American nurserymen and employs one of our cuts as an advertisement of his collection, over which no doubt he claims a proprietor's right.

SOCIETIES AND EXHIBITIONS.

ROYAL BOTANIC SOCIETY.

APRIL 20.

THE second show of the present season was held on the above date, the weather being most genial, the exhibits varied, and the attendance numerous.

Messrs. Paul and Sons, the Old Nurseries, Cheshunt, sent a very fine group of Roses, consisting principally of standards. Amongst the most notable were Baron de Bonstetten, very dark crimson; Madame Lambert, bright rose; Anna Ollivier, large and full flesh colour; Rubens, white with a tinge of fawn colour and suffused with rose; Jean Ducher, salmon shaded with rose, fine form; Saturno, soft apricot; Madame Hippolyte Jaunin, white with a bronzy tint, beautiful in the bud; Her Majesty, large and full, rosy pink. Another excellent group of Roses was staged by Mr. Rumsey, Joynings's Nursery, Waltham Cross. These were both standards and dwarfs. Notable amongst them were Marie Van Houtte, a superb variety, white tinged with yellow, the petals tipped with rose; Maréchal Niel, deeply coloured (this was growing upon the Brier); Madame Gabriel Luizet, satiny pink, large, well formed; Duke of Edinburgh, fine shape, rich vermilion; Lady Mary Fitzwilliam, soft flesh colour; Souvenir d'un Ami, very large, bright rose; Charles Levebre, brilliant red, very fine (this variety was trained as a standard upon its own roots, in which way it is said to produce the finest flowers); and Camille Bernardin, bright crimson. A silver medal was awarded in each case.

Groups of cut Narcissi came from Mr. T. S. Ware, of Hale Farm Nursery, Tottenham, and from Messrs. Barr and Sons, of King Street, Covent Garden, each being awarded a bronze medal. Messrs. Collins and Gabriel, 39, Waterloo Road, London, also exhibited a similar group, combined with a collection of very fine single Anemones, to which a bronze medal was given. Messrs. Veitch and Sons, King's Road, Chelsea, exhibited a collection, not for competition, in which the flowers were all very fine and fresh. Horsfield and Sir Watkin being specially remarkable. We cannot but think the flowers in all these groups were too much crowded, and the absence of their own foliage considerably detracted from their beauty. The most conspicuous flowers in these groups were Sir Watkin, Horsfield, Emperor, Golden Spar, maximus, Leedsi, Mary Anderson, cernuus, cernuus plenus, princeps, moschatas, Empress, capax, Stella, ornatus, cyclamineus, and corbularia conspicua.

A very fine collection of hardy Primroses came from Mr. A. Waterer, Knap Hill Nursery, Woking, and deservedly obtained the silver medal awarded them, forming as they did one of the chief attractions of the show. The group occupied a stage some 50 feet in length. The numerous plants are robust in habit and most floriferous, whilst the colours are so varied that description is impossible. Those lovers of outdoor gardens will find unlimited scope for their tastes in the varied and beautiful colours of these lovely Primroses.

Mr. B. S. Williams sent a large and varied group, a admirably arranged, which was deservedly awarded a small silver medal. Amongst the plants, Palms, Dracenas, Orchids and Ferns were conspicuous; these were interspersed with Liantophyllum minutum, Ochma multiflora, various fine Amaryllids, Au-

thurium Rothschildianum, vigorous finely bloomed Erica Cavendishi, the curious Ataccia cristata, &c.

Mr. Laing, The Nurseries, Forest Hill, sent a large group of miscellaneous plants, not for competition. Amongst them were numerous Orchids, noteworthy being Dendrobium Wardianum, crassinode, Devonianum, Jamesianum, and timbratum oculatum, Odontoglossum, Cattleyas, and the curious and rare Calanthe discolor.

Messrs. Low and Co., of the Clapton Nurseries, staged a fine group of Odontoglossum Roezli and Roezli alba, with very large flowers, a similar batch of O. Alexandre, beautiful varieties, Dendrobium lituiflorum, Cypripedium Lawrenceanum, C. ciliolare, and a very large form of Dendrobium Wardianum called Lowi. Messrs. Lane & Sons, Berkhamstead, exhibited a beautiful group of Azalea mollis, large and varied in colour, also a fine group of Rhododendrons and Azaleas. Anthurium Scherzerianum, Clark's variety, shown by Mr. James, of Norwood, is a fine seedling form with large, flat, cordate-shaped brilliantly coloured spathes.

Ferns came from Mr. H. B. May, of Edmonton, amongst which were good examples of Gymnogrammas, Cheilanthes, Cincinalis, Lencostegias, Davallias, Adiantums, Doryopteris, Aspleniums, Pteris Mayi and P. tremula floecida (both of which received certificates). A large bronze medal was awarded for the group.

Messrs. Paul and Sons, Cheshunt, sent a group of Amaryllids, amongst which were Thackeray, a large, well-formed, bright scarlet flower, with white star; Walter Besant, white, streaked with deep red; George Elliott, a very large, deep red flower; and Eldorado, which would appear to be the precursor of a yellow flower, pale lemon colour, with a few streaks of red; and also A. R. D. Blackmore, a somewhat small flower, white, centre of petals flaked with fiery red, which received a certificate; Charles Kingsley, deep blood-red, white star, &c.

Amaryllids also came from Messrs. Veitch. They were Edith Wymie, which received a certificate; King of Crimson, Guy Manning, fine form, brilliant red, with pale green star; Ovid, a white flower, flaked with red, having two spikes from one bulb, each bearing six blooms. Mr. Douglas's group contained Hilda, bright scarlet, with white star, very fine, which was deservedly certificated; Hero, a large, good-shaped flower, deep crimson-scarlet, with greenish white star. Groups of Indian Azaleas in the amateurs' class came from Mr. Wheeler, gardener to Lady Goldsmid, St. John's Lodge, Regent's Park; Mr. Eason, gardener to Mr. B. Nonkes, Hope Cottage, Highgate; and Mr. Wesker, gardener to Mr. Heaver, Tooting. Amongst the most notable forms were Charmer, Stella, Duc and Duchesse de Nassau, Roi de Hollande, and Ferdinand Keglejan. The exhibitors in the nurserymen's class were Mr. Turner, of Slough, Mr. James, of Norwood, and Mr. Wells, of Sydenham. Notable in their collections were the following varieties: Apollo, a fine single white; Jean Yeryaene, with plain scarlet flowers and others variegated; J. G. Veitch, and E. H. Braudi, a fine large semi-double white.

Cyclamens came from Mr. J. Odell—Queen of Crimson, a large, bold, deep crimson flower, and majesticum, a gigantic flower, white with a rosy magenta throat; the latter received a certificate.

Mr. James sent Cinerarias, of which the following were certificated, viz., Eclipse, crimson self; Ariel, rosy mauve; Royalty, a grand deep blue self; and Jubilee, white flaked with magenta. Cinerarias also came from Mr. Salter, Selborne, Streatham.

Groups of alpine and hardy herbaceous plants came from Messrs. Paul and Sons, the Old Nurseries, and from Mr. Ware, of Tottenham. In the former the most notable were various Primulas, Houstonia erulea, hardy Cyclamens, Scillas, Adonis vernalis, Epigaea repens, Saxifraga aretioides precox, Fritillaria, &c.; the latter group was remarkable for its rich variety of Indian and other Primroses, such as the lovely forms rosea and nivalis, cashmeriana, denticulata, spectabilis, marginata, and others; Fritillaria Moggridgei, Orchis, Sambucina lutea, and various Saxifrages and Anemones.

Auriculas came from Mr. Chas. Turner, of Slough, Mr. Douglas, of Hford, and Paul and Sons, both show and alpine forms. The following new kinds received certificates. Mr. Douglas, for A. Montrose, Rev. Chas. Kingsley, and Tiresias.

Messrs. W. Paul and Sons, Waltham Cross, sent two new Roses, viz., American Beauty, a very large rosy pink flower; and the Puritan—the latter received a certificate.

Mr. Chambers sent a large quantity of his Violet Victoria, which appears to be an abundant bloomer with large deep purple flowers, which are very fragrant. A certificate was awarded.

Pelargoniums came from Mr. Phillips, Langley Broom, Slough; amongst which we noted as very fine, Martial, Mme. Thibaut, Grand Lilas, Rosetta, Duchess of Edinburgh, and Duchess of Bedford.

Tree Carnations were staged by Mr. Chas. Turner, Slough.

A detailed prize list will be found in our advertising columns.

LAW.

OVERSEERS OF LEWISHAM F. H. J. COBB.

AT the Greenwich Police Court on Wednesday, before Mr. Montagu Williams, this case, mentioned in our columns last week, was resumed. On behalf of Mr. Cobb, it was contended that by section 211 of the Public Health Act he could only be rated at one-fourth for his nursery. This was objected to on the grounds that the Public Health Act did not apply to the metropolitan district, except where a special provision was made, and that an objection which was raised to the mode of assessment would be outside his Worship's jurisdiction. Mr. Montagu Williams made an order for the payment of the rates, remarking that the case at Werthing was somewhat different to this, inasmuch as he understood that there was no dwelling-house in that case.

Death of Mr. Richard Carr. It is with great regret that we have to announce the death of Mr. Carr, the excellent gardener on the Duke of Portland's (Wellbeck) estate, from an accident at Redford Station on Wednesday, the 12th inst. He was on his way from London to Worsop, and, having to change at the above station, attempted to get out of the carriage, but in doing so he alighted on one of the steps of the continuous footboard below, and, in consequence, was dragged along and crushed against the platform. When extricated, it was found that he had received severe internal injuries, to which he succumbed. Mr. Carr was highly respected by his employer and by all with whom he came in contact. He leaves a widow with seven sons and a daughter to mourn his loss.

Mr. Thomas Bailey.—We have also to record the death, at the ripe age of eighty-one, of Mr. Bailey, who for nearly fifty years has had charge of the gardens at Shardeloes. He was one of the best gardeners in England, and won for many years the highest fruit prizes at the Botanic Society's exhibitions when the fruit shows there were the best of the kind about London. He will also be remembered for the fine specimens of Pelargoniums which he used to cultivate so well.

H.—Anemone hortensis pavonina, Primula officinalis vulgaris hybrid; Mackaya bella. — D., *Gloucester.*—1, Solanum jasminoides, should be hardy with you; 2, Calceolaria violacea. — H. E. G.—Climber next week; Dendrobium htiflorum. — J. P., *Worcester.*—1, Dendrobium aretaceum; 2, P. primulinum — A. L., *Sussex.*—Quite a common occurrence in the variety of Fuchsia you send. — E. P., *Oxford.*—The lilac flower is Dicentra formosa; Saxifraga oppositifolia, Pulmonaria officinalis.

WOODS & FORESTS.

"YORKSHIREMAN."

FORESTRY NOTES.

RING-SHAKEN TREES.—Have any of your correspondents noticed that dead Oak trees are seldom ring-shaken, the evil being mostly found in living trees? This ring-shake prevails to such an extent in some woods and in certain localities, as to demand more attention from foresters than it has yet received. No timber merchant will buy ring shaken timber, and when woods get the name of being affected that way it hurts the sales greatly. We have one of the largest Oak woods in England here, and it is remarkable to what extent the shaken timber varies in quantity in different parts of the wood, and the fact is just as well known to all the timber merchants of the district as to ourselves. The altitude of different parts of the wood varies to the extent of 500 feet, but the shaken trees are found in the highest and lowest parts alike, and among large and small trees. The only fact seemingly bearing on the cause is that there are most shaken trees on the wettest ground. In some cases large trees that would be worth a good few pounds if sound are found to be almost worthless, and when sawn up just falling to pieces. Whether severe frosts or drought or both are the cause of the rotting of the rings one cannot be sure, and little or no explanation of the matter has ever been attempted, so far as I know. I am inclined to think, however, that on well drained ground the evil is likely to be least; hence, whether the trees be young or old, it is wise to provide drainage, at least to carry off the surface-water.

THINNING PLANTATIONS.—“Caledonius’s” complaints on the subject of hedgerow timber I can well understand, and I hope he will do his best to dispel some of the darkness that exists on the subject of timber-production in Scotland, from which the most determined advocates of severe thinning on the hedgerow principle mostly hail. If, as the rubbishy sermon on forestry at the Edinburgh exhibition inculcates, the light must permeate all parts of the wood in order to produce good timber, why, then, hedgerow trees ought to surpass all others as timber, but “Caledonius,” I can see, has found, by the test of all tests, the timber market, how useless it is. It is the same everywhere. I cannot give “Caledonius” offhand the proper distances at which good trees can be grown, but I promise to do so as soon as I have time, for although examples of mature plantations judiciously planted and grown are all but impossible to find, still any practical man may tell from isolated examples on any estate how much room any kind of tree requires to produce a certain bulk of straight and clean timber. I would just at present point out to such earnest and inquiring patrons of arboriculture as Sir John Lubbeck, whose purpose is good, that even at the present unprecedentedly low values, almost any quantity of good, straight, and tall Oak, Ash, Sycamore, Beech, Birch, Alder, Larch, and Firs can be grown and sold at prices sufficiently remunerative to make timber growing a profitable investment. The one hindrance to that hitherto has been the utterly stupid and extravagant system of planting and thinning in vogue. The quantity of saleable timber that can be grown to mature size per acre when the trees are of the same sort or habit is not realised, but when it can be proved that even cheap Spruce poles can be grown to pay well, there can be no question about the more valuable woods. My own conviction at present is that from 300

to 500 good useful Ash, Sycamore, Larch, or Fir poles can be grown to the acre in from fifty to sixty years at from 5s. to 15s. apiece, but certainly not on the principle of permitting light and air to every part of the wood, which would have the effect of reducing the quality of the timber and its value immensely. Such quantities or more to the acre are, I am told, common in the natural forests in Europe and America, and from these the fine planks and logs come that crush English timber out of the market.

Reverting to hedgerow timber, landlords cannot realise too clearly that it is nothing but an encumbrance to the land, alike profitless to them and to their tenants. Isolated trees in hedgerows are also almost worthless for purposes of shelter. Where such is needed it should take the form of a solid belt or plantation that would serve as a shelter and produce timber at the same time.

THE TIMBER TRADE.—Purchasers say that although the turn over is greater than ever, profits to middlemen are low. The extent of the consumption in such times as these of rough home-grown timber is great. In this district on a few estates adjoining, probably half a million cubic feet has been felled and sent to market during the past year, and it seems as if quite as much will leave the woods this season. One of the puzzles of sales is the difference of prices realised even when lots are sold by auction. We fear that timber growers are rather too much at the mercy of timber dealers in this matter. We notice that the same men as a rule attend the same sales year after year and buy the same lots, other buyers abstaining from bidding for fear of creating competition on their own ground. It is significant the tacit understanding that exists among members of the trade on these matters, and its effects on prices I fear unfavourable.

TREES FOR SHELTER BELTS.

In a district in an adjoining county which I have recently visited I have come across some examples of this class of planting. Trees of all sorts have been used, but perhaps the Scotch Fir is the most abundant. In any case it is the tree which first arrests attention. Whether on financial grounds the very extensive use of this Pine is advisable is open to question, but it cannot be denied that its effect in masses and belts is very good. Very much, however, depends upon how and where it is used. For use in single lines the Scotch Fir does not generally appear to advantage. Amongst the plantations which at the present season show to the best advantage are those where both evergreen and deciduous trees have been adopted. I do not mean by this where they have been mixed pell-mell, but where judgment has been used in the arrangement. In one case I noticed a broad belt which had been planted upon a gentle ascent. The bulk of this consisted of Scotch and Spruce, but the foreground was planted with Larch, the extreme outskirts being Birch. This belt, well to the west or north-west of the house, breaks the cold winds, and at the same time catches the morning sun. At the time I was on the spot the morning was especially brilliant, and the dark foliage of the Scotch and Spruce in the background, with the bare brown branches of the Larch and the silvery white of the Birch in front, had a very pretty effect. If the order of planting had been reversed, and the Larch and Birch placed to the windward, this effect would have been lost, and as a shelter or a timber investment the belt would not have been any better. It is obvious from this that very much depends on arrangement, not merely in the groups in the ornamental grounds proper, but in plantations or belts which are distinctly seen from them. In the arrangement I have spoken of, the views of those who object to mixed planting are directly met, as by giving dis-

inct lines to each tree there is no overcrowding or smothering of one species by another. On the highest ground at the back we have two-thirds of the space covered with Scotch and Spruce in regular order—the lowest ground in front with a third the width of the belt in Larch and Birch. In this class of plantation there is little or no underwood, and in the interior the stems are generally bare to the top. Quite another style of wind-break or shelter belt is that composed of Birch, Alder, and other similar species in the form of underwood or poles. These, however, require judgment in making the periodical cuttings, otherwise if a complete clearance is made, a year must elapse before shelter is again obtained. This could be obviated by taking a longitudinal cutting of half the width of the belt. This done alternately would always leave a sufficient screen. In these belt plantations Beech is often considerably used, not infrequently in conjunction with Ash. In some instances species are very much mixed indeed. As a rule, for timber production I am not much in favour of these mixed plantations, but it must be admitted that occasionally a long price is realised for such. In some cases lately where the Ash has been sold from these mixed plantations it has shown a respectable total.

Where one kind of tree is rigidly adhered to in planting, it either pays well or is worth nothing. Where the species are mixed, it generally happens that one or more at the time of felling are worth a good figure, such as is at present the case with the Ash. There is one thing of which I am firmly convinced in connection with this plantation question, and that is, the evils of excessive thinning and lopping. What is done in this direction must be done when the plantations are very young or not at all, and when the young trees are cut out with mathematical precision the chances are greatly in favour of the trees being sacrificed, which, if left, would have ultimately been the best timber-producers. That young trees should be cared for until they are sufficiently established to overcome weeds and other rubbish, which will generally be pretty abundant, all will agree, but after this my experience leads me to believe the less interference there is on the part of the forester the better. D. J. Y.

Leafing of the Oak.—For many springs I have noticed the varied tints in an Oak wood, and found on a closer inspection that one tree will be nearly in full leaf with the shoots 2 inches or 3 inches in length, whilst in another close beside it the buds will have hardly begun to swell. I am unable to account for it, and it has often puzzled me; neither soil nor situation has anything to do with this great difference, and we must inquire whether it is due to different varieties, and if the acorns from an early tree will produce earlier plants, and whether there is any difference in the timber, or in the hardness of the plants?—J. S. R.

The Silver Birch.—I have often felt surprised that this tree should not be more extensively planted in pleasure grounds, parks, and on large estates generally than it is. In manner of growth it is so graceful, so distinct from all other forest or hardy trees, as to render it eminently fitted for purposes of isolation. A large well-developed tree, so placed that its natural habit is fully displayed, forms a very pleasing feature in the garden landscape, not only when in full leaf, but also during the winter months, when, denuded of foliage, its characteristic features are more fully revealed. The graceful, spray-like pendulous growth and silvery bark show up charmingly against the fresh bright turf of a well-kept lawn, a tree dotted here and there about pleasure grounds doing much towards relieving them of their sameness, and where Evergreens are largely employed, the rather sombre aspect during the dull months of the year. There are, however, a variety of ways in which the Silver Birch might be employed. It has a very pretty appearance when so placed among coniferous trees and evergreen shrubs that they form a background to it, in such a manner that the head of the Birch stands out clear and well defined, whilst the white stem is as it were framed in verdure. In parks, good use might be made of this tree by grouping it here and

there in such a manner that the bright stems would be distinctly visible when the foliage was off. I may mention, however, that there is considerable variety amongst the Silver Birches—some having the bark much more silvery than others, and having consequently, from an ornamental point of view, a much higher value. It is a pity that seeds should be saved from inferior varieties. Were a rigorous selection made, choosing only those trees remarkable for their clean white bark, a great improvement would in the course of time be manifested, and the value of this tree from a decorative point of view would be sensibly increased.—J. C.

SNOWSTORMS AND OAK WOODS.

THE woods as well as the ornamental grounds have suffered from the snowstorms. The Oak especially seems to have come in for a considerable amount of damage. A large Oak wood with which I have to do presents rather a singular appearance. The trees average perhaps a foot in diameter, and are regularly distributed. In the portions where the underwood has been cut within the last few years the damage is most easily seen. The damage chiefly consists in the splintering of branches, though some are broken completely off. The degree of damage varies a good deal. In the worst cases large limbs have been torn away close to the stems, and also here and there portions of the main stem itself. In not a few instances the trees will have to be removed altogether. It is here that judgment is necessary. To fell a tree which is in a healthy, growing state, and leave a blank in a wood where it is wanted for the sake of the crop, means a considerable loss. To leave it for any length of time in such an injured condition, that the chances are greatly in favour of its decaying is worse. A little information from foresters and others who have been able to observe the effect in after years upon Oaks which have been badly torn under similar circumstances would be valuable.

There are few instances in the case under notice where more than one large branch forming a portion, perhaps a third, of the head has been broken. The splintering averages from a foot to a yard down the stem of the tree. The fractures, however, are mostly superficial, and do not go more than an inch or two into the wood of the stem. The temptations to simply trim off the rounded part as neatly as possible, and leave the tree to recover itself if it will, are great in the majority of cases. At any rate, there is no cause for precipitate action, as a season or two would not severely injure what remains of the tree, but would be long enough to form a fair estimate of the way in which the damage was likely to affect it ultimately.

Where trees so damaged are standing in underwood which will be ready for cutting in a year or two, the wisdom of biding the time is still more obvious. In such cases as little as possible should be done to the damaged trees in order to avoid interfering with the underwood. Where branches are partially suspended, and the splintering is very bad, it will be necessary to free the trees, but it will be better to allow what is removed in this way to lie where it falls than to attempt to clear it away. The minor cases of breakage will be more easy to deal with, as when they occur close to, or nearly close to, the stem or a main limb, the fractured portions should be cleanly trimmed close up to the part from which they grew. This is important, as by allowing ragged stumps to remain, they cannot fail to be highly detrimental to the ultimate worth of the tree. Where the branches have been torn completely in two several feet from their junction with a large branch on the main stem, it will be better to simply foreshorten them by means of a clean cut. The actual cost will not be very heavy, as where it is accessible the wood which has been broken off will go a good way towards paying for the labour. In the wood of which I have been speaking, as the trees themselves are not large, few of the broken branches will be of use for anything except firewood. In a few instances mound posts may be cut out, but generally with damaged wood of this sort trees must average, say, 20 feet cubic before much usable material will be found amongst the wreckage.

In connection with this it would be interesting to hear how woods and plantations on exposed hill-sides fared during these storms. This particular wood occupied a comparatively sheltered site. With regard to the telegraphs, I have been told that they suffered less on exposed downs than on the level, or in low situations. This, I presume, must have been owing to the snow having little opportunity to accumulate on the wires where the wind caused a continual movement. How far this would hold good in the case of plantations I cannot say, but there certainly is a difference between the character of the wreckage after a snowstorm and that after a gale of wind. D. J. Y.

MISMANAGED TREES.

IN suggesting the necessity for uprooting a tree, however much misplaced it may be or injurious to other trees of greater importance, we generally meet with as much repugnance as one would encounter in a proposition for removing a house, unless the individual happens to have some knowledge of arboriculture or is acquainted with the principles of landscape gardening. Hence, may be seen in nineteen-twentieths of such places as those under consideration innumerable instances amongst the trees and shrubs of a struggle for life that goes on until a portion, and generally those of the greatest importance, die, leaving those behind half killed and in a condition from which they never recover, through the effects of the fight for food and air in which root and branch have so long been engaged. The fatal effects of this overcrowding are most apparent after seasons such as the present, when the comparative absence of water in the soil through the spring is followed by a hot, dry, rainless summer.

Throughout the country, in extensive tracts of land, resting on a sand or gravelly stratum, the soil at the present time in which the roots of the trees are placed is as dry almost as the dust on the surface, and which the ordinary rainfall of any single season will never moisten. Where trees are too much crowded in dry seasons their roots extract the moisture from the subsoil to such an extent as almost to preclude the possibility of its afterwards becoming moistened deep down, where the principal feeding roots exist. Frequently in removing trees so placed even after very wet seasons, I have found that when the first 2 feet of the surface soil were removed the earth underneath was as dry as dust, the water evidently having found its way further out from an apparent inability to enter the dry, impervious mass which, in all probability, when once reduced to this state, never after gets sufficiently moistened to be in a condition fit for the support of healthy vegetable life. Again, on the boundary line of places such as those under consideration, how often do we see good intentions defeated through mismanagement? To secure the desired privacy, or hide something objectionable, trees are planted with little or imperfect preparation of the ground, which just receives a shallow digging, after that they are planted as closely as possible, the intention being to accomplish the object in the least possible time, forgetting that, however good the land may be, there is still a limit to its capabilities in supporting vegetable life.

In exposed situations sufficiently close planting is necessary, the harder trees acting as nurses to such as are more tender; but too often we see the nurses, instead of being removed when their services have ceased to be required, allowed to remain all intergrown, until the under branches of the whole are destroyed, leaving the weakly attenuated stems standing like a plantation of clothes-props, showing most objectionably their inability to fulfil the purpose for which they were planted. In all cases such as those in question, the preparation of the land should be of a nature to give a reasonable chance for the well-doing of the trees after they have been planted. This cannot possibly be done unless the ground is trenched 2 feet deep, if its character is such as to admit of this depth. The trees should be judiciously selected with a view to their adaptability to the nature of soil and locality, and not too closely planted; as they grow up, thin-

ning should be carried out with judgment, and a the proper time.

Where the treatment is in accordance with these simple rules, especially as to timely thinning, there need be little anxiety as to the result. I have frequently remarked that a great number of people in planting forget that the trees they plant will ever get any larger; and that others appear to think that everything planted should be allowed to remain for time indefinite. In the inner or more central parts of suburban places, in addition to the mistaken management of the existent trees, any after-planting that is carried out is often of the most objectionable character, not only as to the description of the trees selected, but the position in which they are placed and the preparation of the ground.

In the selection preference is frequently given to coniferous trees, the whole of our fine deciduous trees being excluded. A greater mistake than this cannot possibly be committed, if we think of the distant future; for the time will inevitably come when the existent deciduous trees will decay, leaving nothing to take their places except such of the Conifers as are ultimately found capable of withstanding the severest frosts experienced at long intervals. Then, as to position; instead of leaving the all-essential open vistas, so indispensable to give breadth, repose, and impart general effect, the dotting system is perpetrated, having much the appearance of an orchard on a large scale, with the trees at more than ordinary, though regular, distances apart. This is a glaring mistake, and one that is much on the increase.

If we come nearer the mansion how often do we see a Wellingtonia, or some other monarch of the forest, placed so near that by the time it has fairly begun to show its character it will become a matter of necessity to remove either the tree or the house. In the preparations for planting these trees the common mistake is often made of digging the ground over a considerable depth without anything in the shape of a drain to carry off the water that is certain to accumulate in the newly-loosened soil, which acts as a receptacle for the water that drains into it from the surrounding ground, thus precluding the possibility of the tree so placed thriving as it should do. B. T.

Picea concolor.—This fine Conifer is easily distinguished by the irregular arrangement of the leaves; they do not form a row on either side of the stem, as in most of the Piceas, but grow from the top and even the bottom of the branches; they are about 2 inches long, of a whitish blue changing to pale green as they grow old, the upper and lower surfaces being of the same colour. The cones are borne in an upright manner singly on the branches, and are from 3 inches to 4 inches long. As a tree its colour is very pleasing, and it deserves to be more extensively planted than it is, being very symmetrical and free as regards growth. It should be planted in elevated positions in preference to low lying lands, for although it grows very freely in the latter, it is somewhat liable to be cut by spring frosts. *P. Lowiana* and *Parsonsiana* are often confounded with *P. concolor*, but they differ in the leaves being somewhat longer and arranged in a regular row on each side of the stem; they then curve gracefully upward, and form, as it were, an inverted arch. *P. concolor* is freely distributed throughout California, where it attains the dimensions of a large-sized tree. A.

The Aronian Thorn.—This species (*Crataegus Aronia*), indigenous to Greece, as well as several other countries in the south-east of Europe, and introduced in 1810, is a distinct-looking handsome tree of about 25 feet in height. It has a very densely branched, rather erect habit of growth; the leaves are wedge-shaped at the base, deeply lobed, and toothed at the edges; the young shoots and under surface of the leaves are slightly pubescent. The flowers, which generally expand in June, are white, followed by large yellow fruit which ripen in September and are very ornamental. It is an interesting park or avenue tree. — G.

"This is an Art
Which does mend Nature: change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

ROSE GARDEN.

T. W. GIRDLESTONE.

NAMING ROSES.

With the arrival of the new Roses of the year comes a whole series of questions with regard to the naming of seedling varieties, a proceeding which certainly seems in many cases about as inconveniently managed as may be, owing either to the inordinate length of the names employed, or to the casual way in which the same name is applied to different varieties though sometimes, by translation of its title, one variety finds itself possessed of several names), or else to the great difficulty in pronouncing the name selected. That the nuisance of names "long enough to have a perspective" is not abated, the current list of novelties affords the usual evidence. Madame Edouard de Bonnières de Wierre, though an attractive Rose, has more name than any one variety ought fairly to be asked to carry, and Comtesse de Rosemont-Chabot de Lussay is hardly better off. It is said that the original full style and title of a once widely grown variety was Souvenir de la Voyage de sa Majesté la Reine d'Angleterre, but even if that were at all exaggerated, such names as *Sœur Bernède de Saint-Vincent de Paul*, *Nouveau deuil de l'Archevêque de Paris*, *Mademoiselle Eugénie Leprovost de Launay*, *Deuil de l'Amiral Dumont d'Urville*, *Impératrice Marie Féodorowna de Russie*, and so on, are, to say the least, exceedingly unpractical. Not long ago we were treated to *Fiançailles de la Princesse Stéphanie et de l'Archiduc Rodolphe*, with the result that this Rose is now known under four other appellations formed from the names of the happy couple either separately or together; and in the same year a good dark Rose was relegated to the limbo of obscurity almost untried owing to hardly anyone venturing to face such a name as *Comte Frédéric de Thun-Hohenstein*. A Hybrid Perpetual that is still esteemed as a pot Rose in some places has for several years dragged on its existence as *Mlle. Berthe du Mesnil de Montchauveau*. One almost wishes that such a Rose might enjoy the opportunity not always denied to a young lady of changing its name. The objections to these interminably long names are numerous. In the first place, the possession of such seriously prejudices a Rose's chance of getting widely into cultivation, for people will not be bothered with a variety whose name cannot be anything like included on an ordinary label and is as inconvenient to remember as to pronounce. Again, though foreigners have been said always to spell better than they pronounce, yet, however these long names may fare in their own country, the spelling of them here quickly becomes highly diversified. An instance in point is *Constantin Petriakoff*, the changes upon whose patronymic have been so persistently rung, that at the present time probably there is not a Rose catalogue or horticultural print in the country that does not call him *Petriakoff* or *Tretiakoff*, or by some other amended title. Then the practice above alluded to of employing parts only of a very long name is fraught with inconvenience, for no two growers will ever use the same abbreviation; and where the name is diffi-

cult of pronunciation everyone adopts that section of it which he is best able to utter without danger of loosening his front teeth. In the case referred to, between the two extremes of the pompous *Fiançailles de la Princesse Stéphanie et de l'Archiduc Rodolphe* and the too familiar *Stéphanie* we find the intermediate forms of *Princesse Stéphanie*, as well as of *Archiduc Rodolphe* and the two names combined, so that one never knows where in a catalogue to look for the variety.

It is also unfortunate that the south of France, whither all the world congregates at certain times of the year in search of sunshine, should be so well adapted to Rose-raising, as the seedlings get named after notable visitors, whatever their nationality, and we get such names as *Prince Chipetounzikoff*, *Prince Léon Kotschoubey*, *Prince Wasiltchikoff* (which, by the way, is synonymous with *Tea Duchess of Edinburgh*), *Baronne Peletan de Kinkeline*, *Natascha Metschersky*, *Souvenir de Katia Metschersky*, *Madame Olympe Terestchenko*, and *Madame Elise Stehegolett*. These Roses will never be popular in this country, because people who talk much about them get the reputation in their neighbourhood of habitually using such terrible bad language; but we can afford to leave varieties with this sort of names to cultivators in countries where the machinery is cheap for setting open one's mouth wide enough to allow such words to emerge whole.

Happily, there are no pedantic latinisms employed now-a-days in naming Roses, and Smith's, Jonesiana, and so on no longer tend to confound garden varieties with true species; but an element of confusion undoubtedly exists in the free translations of names in which some growers indulge. It is not true that all the French nurserymen are distributing *M. Geschwind's Erinnerung an Brodas Souvenir de Pain*; but when the *Erlikönig* of one catalogue appears as *Roi des Ames* in another, or when *Boule de Neige* turns up over the water as *Snowball*, catalogue-makers may well ask how they are to arrange their lists. This possibility of translation is a strong argument against the use of fancy names, as the names of persons are at any rate untranslatable, and even titles are sufficiently similar in French and English for it to be immaterial whether a Rose is called *Comtesse d'Oxford* or *Countess of Oxford*.

Another source of great inconvenience is the giving the same name to more than one variety. There are at the present time three Roses involving the name of *Victor Hugo*; a Hybrid Perpetual was called after the great poet, and immediately after his death two other Roses, one a Hybrid Perpetual and one a Tea-scented variety, were dedicated as "souvenirs;" the fourth *Comte de Paris* has just appeared, in addition to two *Comtesse de Paris*, both Hybrid Perpetuals; and the number of names that do double duty, once for a Hybrid Perpetual and the second time for a Tea, is legion. This is entirely inexcusable, as there can never be any lack of names, and the aggravation, when plants of some Tea-scented variety have been ordered, of receiving instead plants of some hybrid which is not in the least wanted, is considerable.

It seems likely that there may be instituted in France before long a French Rose Society more or less on the lines of the National Rose Society in this country, and perhaps such an organisation might be able to modify the most glaring of the abuses of Rose nomenclature, by keeping a register of names, and refusing to enter any names already in use or of extravagant length. But it is probably too much to

hope that any such action would be taken for fear of hurting the feelings of some too-sensitive members: in which case it will have to be left to the good sense of raisers to avoid using names like the procession—so long, that when one end came in view the other was still below the horizon; to have some consideration for the amiable Britannic weakness in negotiating sequences of more than four consecutive consonants; to eschew translations; and, above all, to avoid the employment of names which have been previously given to varieties still in cultivation, whether in the same class or not.

In quest of a Rose.—If you are looking out for Roses I wish you would find the old double yellow. I do not mean *lutea pleno*, which is common enough, but I mean the plant described by Clusius, Gerard, and Parkinson, and well figured in vol. i. of the *Botanical Register*. The plant sent out from Barchley as the old double yellow is quite different. Lindley also describes it.—H. N. ELLA-COMBE.

New Roses. Among the fine display of Roses at South Kensington on the 26th inst., several of the new varieties of 1886 were exhibited by Messrs. Paul, of Cheshunt, including *Her Majesty*, though the variety was not in such grand form as when seen at Cheshunt during the previous week, the flowers staged being rather past their best. The flowers of *Clara Cochet*, on the other hand, were rather young, but seemed in the way of *Catherine Soupert*, but deeper in colour, being a clear fresh pink, with paler edges to the petals. *Raoul Guillard* is a fine-looking globular red flower, of the *Maurice Bernardin* type, and appears good. *Madame Villy*, on the other hand, is a flat, short-petaled variety, of dreary purplish colour, that amateurs will be in no haste to add to their collections, though they cannot be too grateful to exhibitors, who will show them not only what novelties are good, but also what to avoid. T. W. G.

Roses Céline Forestier and Cheshunt Hybrid.—I forward you four flowering shoots of a yellow Rose as a sample of its floriferousness. The one carrying nineteen buds and one fully expanded flower is not at all a solitary example on the tree, as there are at present a great many shoots bearing about the same number of flowers. The tree is planted out in our greenhouse and trained on the roof, and is at present carrying many thousands of flowers fully opened, half opened, and in bud. Along with it in the same house are also the old and well-known *Lamarque* and a red one, of which I send you an example. I do not know the name of the red, unless it is *Duchess of Edinburgh*. They are both flowering very profusely, rendering the house at present very attractive indeed. ALFRED BARKER, *Adare Manor, Limerick*.
* * * The yellow Rose is *Céline Forestier*, one of the hardiest of the Tea-scented section. The red one is *Cheshunt Hybrid*. Both had very fine foliage, and from the samples sent seemed to be in the most robust health.—Ed.

Rose Lamarque.—Those in want of a good climbing Rose cannot do better than plant the variety here named. It grows freely, having a strong constitution, and blooms in profusion just at a time (about Easter) when the flowers, which are pure white in the bud, are in great demand. When the flower is half expanded, the centre of it shows a pale yellow hue, which deepens as expansion takes place. The perfume of this variety is very pleasing, and its free-flowering qualities are very remarkable, the blooms being borne in clusters of four and six together at the points of the current year's growth. It is a variety which also lasts a long time after being cut, which is best done in the bud state in the morning. It is not necessary to train the shoots of this variety so thinly under the roof as some other kinds. When the blooming season is over cut out some of the oldest branches, selecting those which are weakest and unlikely to produce young succulent growths the following season. Thoroughly syringe the foliage during the summer, thus procuring a

healthy free growth, which is indispensable to an ample supply of choice flowers. It grows well on its own roots. Cuttings taken off at this stage with a heel quickly form roots, and make nice plants in a short time if the pots are plunged in a gentle bottom-heat and shaded from hot sun.—E. M.

* * The blooms sent by our correspondent well bear out his remarks. This Rose ought to be grown much more than it is at the present time, as from its free vigorous growth, floriferous character, and good qualities when in the bud state, it will well repay all the attention that may be bestowed upon it.—Ed.

EDITOR'S TABLE.

"Went out at early morning when the air
Is delicate with some last starry touch,
To make sure
At worst that there were Roses in the world."
ELIZABETH B. BROWNING.

ROSE CLIMBING DEVONIENSIS.—A bunch of the large, soft, delicately-coloured blooms of this great Rose, from one of the fine old London suburban houses not yet absorbed in the "wen"—The Oaks, Epsom.

I here enclose you a small gathering of our favourite Rose here—Devoniensis (climbing). Although we grow other Roses, both Teas and Hybrid Perpetuals, the demand for them ceases immediately this comes in. We have two plants of it in the conservatory, each covering a superficial area of 200 feet, and from each we can cut hundreds of the most beautiful buds weekly. There are many more free-flowering Roses, but none, I think, more charming in the bud or half-open state. The deep carnation tint of some—and this puzzles me, as you find them only here and there on both plants, in shade and exposure—is truly exquisite, and sure to charm those seeing it for the first time; while the scent is, I think, the best of the Teas. It is almost pitiful to see a Belle Lyonnaise in the same house, crowded as it is with thousands of flowers, passed by the ladies without comment, to bestow all their praise on what I may well name here the "ladies' favourite."—J. KNIGHT, Epsom.

*

MISS WHITAKER sends me from Bryn Calyn, near Pwllheli, some Freesias.

I am sending a few Freesias for your "table" as a proof how easily these pretty flowers can be grown in merely a cold frame through the winter, and, by exposure to sun and air on fine days, can be blossomed early in an open situation in South Carnarvonshire, North Wales. I also send a few Sanguinaria flowers, which are growing in a peat bed amongst Indian Azaleas (the latter having stood the late severe winter well in the open air). With Ivy leaves and the red-tinted leaves of the wild Pelargonium, the Sanguinaria flowers make a pretty combination.

The common Ivy leaves remind me, by their beautiful bronzy hues, that our best hardy evergreen is also, perhaps, our prettiest fine-leaved plant, especially to those who observe its lacework in our woods in winter around Oak and other stumps. The Bloodroot travelled very well, although it is so fragile that we do not expect it to do that. It is very pretty in the Grass.

*

BLUE-EYED MARY.—This little flower comes to me from Munstead. I have never seen it made much of indoors, but I believe it is capable of great good in various ways. I have done all I could for it under the name of Creeping Forget-me-not, which I gave it (Blue-eyed Mary is its Yorkshire name). I have never seen a garden in which justice has been done to it, yet it has been in our gardens for several generations. It is generally found in some neglected corner. Finding a few tufts last year, I put them in a rather deep border, forming a large colony. They did well in the autumn, and had a fine carpet of leaves, but the hard frost and the blackbirds during the past spring seemed to destroy all the foliage. A few weeks ago, however—so vigorous is the little plant—up came a carpet of beautiful fresh leaves and running shoots, and for some weeks past it has been a mass of beautiful blue flowers. We are hunting the world for novelties. I do not know any plant so easily grown, so pretty, and so neglected as this. It is for everybody's garden.

THE ROSE PRIMROSE.—This Indian Primrose from the open air is very delicate and pretty in colour, and in habit much prettier than the specimens shown the same day in pots at Kensington—a most brilliant flower and not difficult to grow, but especially valuable for those who have rock-gardens made in any sensible way. The lilac and purple Indian Primroses are also very pretty just now, and appear to grow freely under almost any conditions, even after such terrible springs as the present. Handsomest of all, perhaps, most vigorous and delicate in colour, are the forms of our own native Primroses, so happily and well grown at Munstead. Sometimes they are called bunch Primroses, because, like the Oxlip, they push the root-stem up, whereas the common Primrose comes singly from the bottom. Of all flowers for the table, there is scarcely anything better than the common Primrose cut as a plant and put—leaves and all—into some simple basin. After all the hybridising and crossing and talking, there is perhaps nothing better than the common Primrose.

*

GRAPE HYACINTHS.—These delicate Grape Hyacinths, how beautiful they are, old and new! None better than the old pale blue and white, but all interesting, and highly capable, where they are plentiful, of pretty use in the house. The botanical differences are, I fear, minute, but with these we have nothing to do. Beauty is our true goddess.

CHRISTMAS ROSES.—The last of the Christmas Roses, and the Algerian Iris, beautiful things that cheer us in the middle of winter. How delightful this Algerian Iris is, opening so prettily in the very winter, for all who have a bit of sandy, warm soil! Spring Hellebores, with their good leaves and their quaint spots, come in well, though they have scarcely the bright and pure colours of our spring flowers.

THE APENNINE ANEMONE.—Welcome in any shape, but probably not so good on the table as in the Grass. I have for several weeks past had, even from things planted in the autumn, some pretty effects, visible at some distance, with these starry blue flowers. If there were no other plant than this suitable for the wild garden, the thing would be worth taking up. I wish someone would tell me where it is growing plentifully in a wild or semi-wild state.

THE OLD JAPAN PYRUS, ever faithful and brilliant, generally made more of on cottage walls than in large gardens. The new colours and the pale and white forms are excellent additions that ought to be looked after.

THE LARGE PARTRIDGE BERRY (Gaultheria Shalton). Leaves very handsome for going with certain flowers, such as *Andromeda floribunda*.

THE ITALIAN DAFFODILS come in very prettily among the nobler forms that are now in our gardens, and which cannot become too common. The double yellow Narcissi are pretty, some very pale and delicate in colour.

PANSIES.—My favourite and almost everlasting Pansies have been hardly treated this spring, but at last they begin to come. Their refined odour and ever-varying and exquisite beauty of colour make them excellent for the house.

THE SCARLET WINDFLOWER.—The big Aldborough variety, a large and brilliant flower, seems to travel well if gathered in the bud state. Captain Thomas tells me that he sends them with the greatest regularity and safety from Ireland to London.

THE COMMON JONQUIL.—This old friend, a relief among the handsome trumpet and other Narcissi, with which the floral world is now so much engaged.

DOUBLE PRIMROSES.—Forms of our common Primrose, double, somehow never got very plentiful, and yet they are very pretty. The lilac one I saw in great quantity at Plawhatch, perfectly covered with its soft coloured flowers. It is very common in cottage-gardens, but it is rare to see it in large tufts. I wish some of our very pretty old double Primroses could be grown as easily.

"St. BRIGID" sends me some enormous double Poppy Anemones, really like great Poppies. They

are very fine, no doubt, these mixed seedling Anemones, but after trial of them, I think it would be a great advantage if we could separate some of the more brilliant forms, and get them pure. "St. Brigid" is also strong in the bunch Primroses before alluded to. They seem to like Howth very well, and they would be hard to please if they did not. Some of the high coloured Crown Anemones are more effective in colour than the scarlet Windflower in its finest forms.

THE MEXICAN ORANGE FLOWER.—Very fresh and star-like, and more like an Orange in bloom than it is often seen. It is of high value in the cut state from the greenhouse, apart from its valuable qualities as a wall shrub.

BUSH DAISY.—Mr. Hartland sends us one of those interesting Bush Daisies not yet very common in our gardens. It is grown out of doors, and therefore is a valuable addition to our early shrubs. He says:—

The difference between our warm climate and yours, as I saw near London last week, is most marked. The white would make a good photograph. We have had fine showers for the last few days—a great boon. Emperor Daffodil is nearly 3 feet in height and foliage 14 inches across. To talk of growing white Daffodils on the London clay soil is nonsense. It will not grow them.

THE GARDENERS' ORPHANAGE.

I THINK after our very satisfactory meeting of yesterday, and the progress the orphan fund has already made, and, I have no doubt, will make (in spite of the clumsy way it was put before the public), I beg to return my sincere thanks to the members of the press, committee, and our worthy chairman for the very able and willing help they have already given to this scheme. I hope no gardener in the kingdom will let the next three weeks pass without responding heartily to the call of charity.

I think the call from the Gardeners' Benevolent looks more like giving a treat to those already provided for than for giving needed aid. We unfortunately had a sad experience of the need of an orphan fund only a few days since, when our poor brother Carr met with such an untimely end. Whether his widow and children will need help, I know not, but if they do, out of our small beginnings I should suggest rendering them what we can. In starting this scheme, I could not possibly have thought of myself, or that it ever would be useful to me, and I am sure none who have already given me their support will draw back on account of my shortcomings in placing it before the public.—CHARLES PENNY, *The Gardens, Sandringham*.

—A meeting of the committee promoting the above object took place in the conservatory of the Royal Horticultural Society on the 26th inst. Mr. George Deal in the chair. The hon. secretaries reported that over 6000 circulars, setting forth the objects sought to be attained, had been circulated, and that the replies received were regarded as very hopeful for the success of the scheme. The committee decided to prolong the time for receiving replies to their circular until May 7, and as they have decided to introduce into this some modifications of an important character calculated to increase the interest taken in the scheme, a further issue of the amended circular is intended. That the scheme has proved a gratifying success there can be no doubt. It is intended that the children of departmental foremen in nurseries and seed warehouses shall participate in the benefits derived from the fund.

Growing Tea Roses under glass.—Will you kindly inform me in your next issue as to the best book on the cultivation of the Tea Rose under glass?—W. B.

Wedding flowers.—We are informed that all the flowers for the decorations at the Clock House, and part of those at St. Peter's Church, on the occasion of the marriage of Miss Wemyss with Lord H. Grosvenor, came from the Wemyss Castle and Torric House Gardens. Those used in the church were composed of white *Rhododendrons* grown in the open air, and in the Clock House, entirely of Daffodils of the following varieties, viz., *princeps*, *Tekmonius plenus*, *rotundus*, *Horsfieldii*, *incomparabilis*, *Leadis*, *capax*, *aurantius plenus*, *Burri conspicuus*, also a whole table of white Daffodils sent from Torric, from Miss H. M. White, of Charleville, from Miss Owen, of Knockmillen, and from the Rev. G. H. Engleheart. The Daffodil was the bride's favourite flower, and she has herself a large collection.

GIANT GOURDS.

THE largest of the Gourds so commonly grown on the Continent as an article of food, though not often so used in England, are well worth growing for their showy and picturesque qualities. They flourish well and look their best when trained over the roof of a shed or any low building; but it is well to give some kind of stout support or trellis to distribute the weight and avoid the danger of broken tiles or slates. The larger Gourds in the engraving weighed between 90 lbs. and 100 lbs., and were grown in one of the home counties from Messrs. Vilmorin's seed of *Potiron Rouge*. For kitchen use they are by no means to be despised, yielding for some winter months the material for an excellent *purée*. For this purpose they are left

teach him the use of farm and garden implements between his lessons of spelling and reading. Let there be technical schools by all means for those whose tendencies run in particular grooves, but to cram science (so-called) into the raw juvenile is a waste of effort. By far the greater part of mankind must continue to get their living by the sweat of their brows till the end of time, and the best education for the work is to cultivate the powers of observation as far as possible in direct contact with Nature. — E. HORDAY.

KITCHEN GARDEN.

W. WILDSMITH.

PITS AND FRAMES.

OWING to a variety of circumstances, the present season has thus far been the most difficult one

Giant Gourds (*Potiron Rouge*). Engraved for THE GARDEN from a photograph taken at Munstead.

to ripen till the middle of October, and are then stored in a dry fruit room, where they can be cut from as required.

Foolish "education" of gardeners.—It is comforting to an old stager to find a man who can put his foot down firmly on some of the excesses of our educational system (see page 374). Our village schools are in many instances neglecting the common things for the sake of cramming in a smattering of the so-called sciences, from which the pupils never derive any benefit, as superficial knowledge on any subject now-a-days is useless. I grant, of course, that the tendency of all knowledge is to expand the mind. But what expansive power can there be in a few set phrases composed of hard words, which the youngster soon forgets, because in the rush and hurry of his young life he never acquires the meaning of half the hard words temporarily crammed into his little noddle? Better give him practical lessons in the garden or the field, and

we have had to contend with in respect to pit and frame space, and economy being the order of the day, additions to our stock are out of the question, at least other than such as we can ourselves manufacture. To make frames, in the strict sense of that term, is beyond our mechanical ability, but we have devised sundry shelters and modes of protection for early vegetables and kitchen garden seedlings of various kinds that answer so well as to admit of our using the whole of our ordinary pits and frames for *Chrysanthemums*, bedding plants, &c. Early Potatoes, Carrots, Cauliflower, and Lettuce were all planted or sown in ordinary glazed frames, but as the season advanced the above-named plants required more space, with the result that makeshift appliances have been put up in the form of rails, fixed round the sides of the forcing beds, and to these rails have been

tied mats that form a protecting wall to the vegetables. The coverings for the top that are only put over on cold nights are made of tarred felting, tacked to a rough wooden framework. Pits built with soils that are eventually destined for potting soil make excellent shelters in which to prick out Celery, Cauliflower, and the like, as well as for growing the first crop of French Beans, and as hurdles of felting are too expensive, we have placed stout sticks over the turf walls, and use mats and tarred canvas as coverings in bad weather. We are fortunate in having good walls for fruit growing, and at the base of these walls the shelter is so good as to be very little inferior to that obtained from frames, and the movable wall coverings—for the protection of fruit trees—afford the fullest protection to any seeds or plants growing there. At present these spaces are filled with Brussels Sprouts, Cauliflowers, Stocks, Asters, Zinnias, Phloxes, Delphiniums, and Everlastings, and we have just sown there several varieties of herbs and perennial flowering plants. There are several other ways of providing such temporary shelters, and this record of what has been done may prove suggestive to the developing of other modes of protection. A correspondent recently wrote disparagingly of home-grown early vegetables—virtually, in fact, advocated a discontinuation of growing them, on the ground that they could be bought much cheaper than their cost of production in a private garden. I shall not attempt to dispute such an assertion, except to say that such may be the fact; indeed, in respect to the production of early Potatoes and Asparagus, I am quite ready to admit that the writer is right; but most employers, even those that can ill afford means for the production of forced vegetables, prefer to have supplies from their own gardens to having them second hand, notwithstanding that they may be a little cheaper. Taking this view of the matter, I contend that it is only right that home produce should be valued at a higher figure, say at from five to ten per cent. If this be granted, I have no doubt about the growing of early vegetables and salads in private establishments leaving a balance on the right side of the ledger. Personally, we have no choice in the matter: the produce is demanded and no buying in the market permitted, and this is the reason why we have to exercise any little ingenuity we possess to provide shelter and other suitable contrivances to get an early and continuous supply.

Mushrooms.—I was interested in the inquiry about Mushrooms at p. 375, because for some time I have been trying to find out whether Mushrooms grown from reputedly good spawn and grown in prepared beds are injurious or not to those that eat them. With a view to get information on this point I made several inquiries, but the question seems still undecided. True, I did not send a sample of the Mushrooms, but my inquiry stated the fact that Mushrooms grown in pasture fields or in well-made beds are injurious to some people when they eat them. Last autumn one of my family (an adult) was ill for several hours after partaking of Mushrooms collected in a pasture field, while others who partook of them felt no ill effects. Both the hands and legs of the person with whom they disagreed were swollen, and a pricking and itching sensation went on for more than an hour all over the body. My last perplexity in this matter occurred in February of the present year, when an old pupil of mine sent me a box of Mushrooms that I might see how well he was growing them, and a finer lot I never saw. These I divided between my own family and the young men in the garden. Two of my children ate from them two Mushrooms each: one (the elder of the two) was ill within an hour after taking them with pains in the chest and limbs

which symptoms lasted for about three hours, while the other felt no ill effects; neither did the men in the garden who ate them the same day. I have been minute in giving these particulars, because I hope it may lead to obtaining a satisfactory explanation. So far as I can understand the subject, the Mushrooms are not in themselves injurious, but the fact of many people not being able to partake of them proves the truth of the old adage, "that what is good for one is poison for another." J. C. C.

THE HARDIEST VEGETABLES.

AFTER the experience of the past winter it is most probable that more regard will be paid to the work of stocking the kitchen garden with vegetables that can be depended upon to withstand a series of severe frosts. I could point to numerous gardens that early in the winter were literally crowded with various green vegetables, but which now are nearly or quite bare. The old complaint, "gardener's greed," has much to answer for. One phase of this is to plant much more than is really wanted, under the impression that it is better to have too much than not enough of everything. So it is, but when this idea leads to undue crowding, a very different result may be, and oftentimes is, the consequence. What we have to guard against is the planting or sowing in quantity of kinds or sorts of doubtful hardiness, and to always avoid crowding—the latter evil being perhaps most prevalent.

BROCCOLI.—I hold this to be the most serviceable and the most valuable of all winter vegetables, yet, unfortunately, it is among the greatest sufferers during the past winter. As far as the generality of private places is concerned, Broccoli is very scarce indeed, but, if I am rightly informed, the markets will be well supplied from the open fields, as not only do they conduce to a sturdier, and therefore harder, growth, but they seem to improve the quality of either vegetables or fruit. What in a garden may prove of poor quality is altogether superior under intelligent field culture. At least, such is my experience, and I have had good opportunities for proving the truth of the assertion. Although market growers, as a rule, have the advantage of an open position, they do not often plant so thickly as private gardeners are in the habit of doing. In one severe winter I knew a case where a field of Broccoli was sold at the rate of £75 per acre. The variety was the old Cattell's Eclipse, and the plants were disposed 3 feet apart each way. They touched each other all round, but this was very different to what is frequently seen in private gardens, where, oftener than not, the stems of the plants are 2 feet or more high and naked. Early sowing, the plants being allowed to remain in the seed-beds too long, and finally planted on rich ground, perhaps not more than 2 feet apart each way, are sure methods of growing such tall, easily killed plants, and the sooner a more rational plan is adopted, the better it will be for all concerned. Early in May is quite soon enough to sow the bulk of the sorts, and harder, if smaller, plants will eventually result from seed sown towards the end of that month. A good, open seed-bed is to be preferred, and this, coupled with thin sowing, ensures sturdy plants to start with. These should be planted on firm, fairly rich ground, in rows 3 feet apart, and the plants not less than 30 inches asunder in the rows. If disposed among rows of early Potatoes (to plant among late or strong-growing sorts is simply a waste of time), the stems will become rather leggy, and will need to be heavily moulded up directly after the Potatoes are lifted. The latest raised plants seldom attain a great size, and on firm land we plant them 30 inches apart each way. These retain their leaves much better than the earlier raised and more strongly grown plants, and this has much to do with their superior hardiness. We are cutting abundance of fine heads from those planted in succession to Strawberries, these being preferred to much larger ones obtained from the earliest raised plants. What I believe to be the hardest of all Broccoli is Miller's Late Dwarf, but this, unfortunately, does not give close good heads. The old Cattell's Eclipse, of which Mr. Gilbert professes to hold a superior

stock, is both hardy and good in quality, but is not so late, unless specially treated, as Ledsham's Latest of All and Late Queen. Both of the latter produce large creamy white heads of excellent quality, and we have only lost about 10 per cent. by frosts. Veitch's Model is of sturdy habit, and during May invariably yields a good successional supply of close, conical-shaped heads, which, being exceptionally well protected by leaves, are very white and delicately flavoured. It is one of the most distinct and valuable sorts in cultivation. Leamington should also be grown in every garden. It is fairly hardy and very good in other respects. We are cutting it now, and it will be available for another fortnight. Veitch's Autumn Protecting is far from being hardy; but, all the same, we grow it extensively for lifting and storing, no other sort being so serviceable at mid-winter and thereabouts. Seed of this variety ought to be sown early in the spring and again early in May. Spring White, a good variety for March, has proved harder than anticipated, and we have just cleared a good breadth of it. Snow's Winter White is fairly hardy, but if sown before May is quite useless with us. Cooling's Matchless and Champion Late White are also hardy and good, the former being available in April and the latter late in May. The Purple Sprouting is very hardy, and yields abundance of succulent sprouts in the spring.

BORECOLE OR KALE. Cottager's Kale proves exceptionally hardy and profitable, and should be grown where an abundance of greens is needed daily. Scotch Curled, of which Read's Hearting is a desirable form, has withstood a long and severe winter, and gives plenty of good greens. There are none so hardy as the Asparagus or Buda Kale, and either the green or dark-leaved varieties are very profitable in May and June especially, the greens, properly cooked, being very succulent and palatable. The former sorts we raise with the Broccoli, while the Asparagus Kale is sown in drills, any time in June, where the plants are to grow, the rows being disposed 2 feet apart and the plants thinned to about 18 inches apart. It will thrive on a north or east border, and I have never seen it killed anywhere.

BRUSSELS SPROUTS.—From March 14 to the 21st we had a series of sharp frosts, the figures ranging from 15° to 29° of frost. In this neighbourhood, on the night of March 17, I am credibly informed the mercury went down to zero, this being 3° colder than it was here. Such an unusually severe frost naturally cut up things badly, and anything above the snow-line not perfectly hardy at the present time presents the appearance of being scorched. Brussels Sprouts were but little injured by previous severe frosts, but were nearly killed by the March frosts. This being so, they cannot be classed as perfectly hardy, but I have no doubt Mr. Gilbert is right about them. According to his experience, breadths of plants obtained by late sowing, or, say, during April, are the most hardy, and I have no doubt that such is really the case. It is the latest sown Broccoli that are the hardest, and the same remark may reasonably be applied to other members of the Brassica tribe. Younger plants are not only protected by the leaves, but they also possess a greater amount of vitality. Mr. Gilbert claims that his Jubilee Sprouts are quite hardy, but it may be that his method of cultivation has something to do with it. Those he kindly sent me were beautifully green and of excellent quality. These, *No Plus Ultra*, *Perfection*, and other good varieties being now available, there is less need to sow so early as was the case when we had to rely principally upon the imported. Those plants raised under glass and pricked out early eventually grow to a great size, frequently yielding a quantity of early sprouts when not needed, nor really good enough to eat. If a pinch of seed is sown at once and the plants obtained be duly put out on fairly rich ground, at about 30 inches apart each way, they will yield a good supply of late sprouts in all probability even if a very severe winter be experienced. The coarser sorts, of which the Aigbarth may be instanced, have had their day, the flavour of these being objectionably strong, and those that yield close, neat sprouts are rightly replacing them.

No Plus Ultra is now the favourite variety here, and I believe it will give satisfaction wherever tried. . .

CABBAGES.—We have been able to cut really good Cabbages at almost any time throughout the winter. The January and February frosts, although very severe, did not kill any of them, but whether they would have survived the March weather without the covering of snow is rather doubtful. The seed was sown the first week in July, and the plants put out in succession to the spring-sown Onions, a surface being all the preparation the ground received. Last autumn was favourable to a late growth, hence the earliness of the crop. Early sowing sometimes ends in the premature bolting or seeding of the crop, but the risk is worth running, especially if the precaution is taken of sowing again a fortnight later. Our second batch is now commencing to grow strongly. Planting on firm yet good ground—and Onions usually receive liberal treatment, frequently more than they need in fact—tends to check rank growth and induce quicker maturation. Moreover, undug ground does not become saturated, and is therefore warmer than that which is much broken up. Wheeler's Imperial, if obtained true to name, is yet one of the best Cabbages in cultivation, and we also find Ellam's Dwarf Spring and Veitch's Matchless hardy and good in every respect. London or Rosette Cole-wort, sown the first week in June and duly planted out about 1 foot apart each way, affords a capital supply of sweet heads during the early winter months, and Shilling's Queen, similarly treated, is also profitable and good. Chon de Burchley, sown in April and May and planted in rows 2 feet apart and rather closer in the rows, gave a supply of useful heads in succession to the Cole-worts, but as those left were not well covered by snow in March they were cut up badly. It is more serviceable than I at first thought it to be, but it certainly is not so hardy as Mr. Gilbert would have us believe.

SPINACH.—We find Spinach perfectly hardy, and it is almost indispensable. During a showery autumn, slugs usually spoil our beds, and that, too, in spite of almost daily dressings with soot and lime. Last season was an exception to the rule, and we are fortunately enabled to include Spinach in every hamper sent to the town house. The Round or Summer is quite as hardy as the Prickly or Winter, and it is always advisable to make two or more sowings, commencing about the middle of August and following at fortnightly intervals. The rows to be 1 foot apart, and the plants only lightly thinned out, as there are other enemies to the Spinach besides slugs. I hold Winter Spinach to be a most uncertain crop, but luckily we have a good substitute in the shape of Spinach Beet. If seed of the latter is sown at the same time as the ordinary Beet, or even as late as June, and similarly treated, strong plants will result, which will yield abundance of fleshy leaves throughout the winter. It is perfectly hardy, and there is no limit to the supply of leaves a few long rows will yield. The quality cannot be said to quite equal the ordinary Spinach, but in this, as in many other instances, very much depends upon the cooking.

LEEKS.—Generally speaking, Leeks may be said to be the most perfectly hardy green vegetable in cultivation. They are useful, too, good cooks frequently utilising both tops and bottoms, and I believe they are gaining in popularity. A pinch of seed sown in the open ground early in March or as soon as the nature of the soil permits, usually results in a plentiful supply of plants. These when about 9 inches high may be planted 6 inches deep into holes formed with a stout dibber, a little water poured into each hole being all that is necessary to fix the roots. Supposing the ground to have been well manured prior to digging, the Leeks will grow strongly, and eventually will fill the holes, thorough blanching being a sure consequence. We have two very cold north-east borders, and the rotation consists of Leeks one year and Asparagus Kale the next. Large Leeks not being required, we plant them about 1 foot apart each way, but if extra fine ones were in demand, a few would be grown in trenches and treated in every respect similarly to Celery. Ayton Castle is perhaps the most generally

useful sort in cultivation, and if show Leeks are required, both Prizetaker and The Lyon are suitable. W. I.

VEGETABLE PROSPECTS.

SELDOM have kitchen gardens been more bare of produce than this spring. The Broccoli are mostly swept off clean, giving much emphasis to the appeal for more hardy varieties.

Even the spring Cabbages, so called, have been so often frozen and so long under the snow, that it will be long past midsummer before they reach any stage beyond that of thully tufts of green leaves. Even these will be grateful this spring, for in not a few gardens Scotch Kale and even Turnip-tops are either severely enripped or wholly killed.

Brussels Sprouts, that mostly yield some good cuttings at this season of the year, are still almost as dominant as at mid-winter, and promise few pickings till the end of May, if they may cumber the ground so long.

Winter Spinach has also suffered severely, fully two-thirds of our plants being killed outright. A writer says somewhere that the summer Spinach is as hardy as the Flanders. I have never found it so, and have seldom seen such havoc made among the latter as this season. All the Parsley kept for winter use has also been killed down to the ground, a warning to those who neglect the safe old rule of cutting all, except what is needed for a current supply, close to the ground in August. The late leaves will be much smaller and shorter, but likewise very much harder than the longer and grosser ones made in the summer.

The seeds of Onions and other main crops have lain much longer in the ground than usual, but they are now coming up freely and look well. Peas, Broad Beans, &c., are also looking well; but this only applies to spring-sown ones, as I have seldom seen winter-sown Beans and Peas look more rusty and unhealthy. The former are the worst of the two, and in not a few gardens as well as on farms the winter Broad Beans have been turned in. We seldom sow either now, as the risks from severe frosts, slugs, mice, and rats are too numerous and great to make it worth while. But little time is lost by sowing in February or March or even in April in such seasons as these, while seed and time are economised, and better crops as a rule ensured by spring sowing.

HORTUS.

Market Carrots.—Writing upon this subject in a recent issue of THE GARDEN, "A. D." rightly surmises that the growers of the Long Surrey Carrots do not get much more than one penny per bunch. The highest price obtained in Covent Garden this winter has been 2s. 6d. per dozen bunches, and that was when the ground was covered with a deep snow, so that the labour of digging and hauling twenty miles to London was hardly compensated for all that relatively high price. For long, straight, well-coloured roots a common price has been 1s. 6d., and at the present time it has dropped to 1s. 3d. per dozen. For the last decade the prices have been steadily diminishing, so that the grower's profits have at length reached a vanishing point. When rent, expenses of culture, cartage, and salesmen's charges are taken out, there is no margin of profit for the grower at 1s. 6d. per dozen; indeed, I think that at that price he is growing at a loss, and that in the course of a short time the culture of Long Surrey Carrots will be an extinct industry. Only a few years ago the ordinary price for this kind of Carrot was from 3s. to 4s. per dozen bunches, and it generally happened that at some period of the winter the price ran up to 5s. and 6s. per dozen. In a time of hard frost, when green stuff was much cut up or came but sparingly into market, the Surrey Carrot growers had a good time. It is not so much that more Long Surrey Carrots are grown than formerly—for they will only do well on certain soils—as that the fancy of the consumer has changed. Most people now prefer the Intermediate, which, although not so attractive, is of better flavour, and can be produced at a cheaper rate. It will also grow on stiff lands where the Long Surrey

cannot get down, and is grown in enormous quantities in the eastern counties. Many greengrocers who at one time sold only the Long Surrey now merely obtain a few bunches for "dressing" their shops.—J. C. B.

Broccoli growing. It now turns out (p. 376) that it was not "men" Mr. Gilbert wanted to grow Broccoli, since he can now produce any number of "cottagers who can grow all kinds of vegetables better than one-half the gardeners in this country." I do not know what gardeners will think of Mr. Gilbert's compliments, but I rank his statements on that head with his assertions on "hardy" Broccoli and Peach houses, &c., and he has no doubt inferred from what I said on these subjects how much value I attach to them. It appears that when he wrote before he had not made up his mind as to what a hardy Broccoli is; but other people are under no misapprehension on that point. I suppose the editor meant a Broccoli that was hardy enough to stand our severe frosts, like a Brussels Sprout or a Borecole, and that is what I and others mean also. It is not one nor two sharp frosts which will kill Broccoli, but a spell of frost-continued severe cold. Mr. Gilbert's quarters of Victoria have not experienced anything of the kind this season, and, in addition, were probably covered during the whole or a portion of the time he had any frost with snow, the best protection that they can have, but not alluded to by Mr. Gilbert. It is interesting to learn, though, that Mr. Gilbert's *Chou de Burghey* is, now that its *true qualities are known, not "Gilbert's,"* but "*Wright's.*" Also that he, Mr. Gilbert, "never represented it as a Broccoli." I am almost certain that it was sent out as both, and in corroboration of that I here append an authorised description of it from a noted seed catalogue (Backhouse) only this year:—

CHOU DE BURGHEY.—A new vegetable raised by Mr. Gilbert, combining the good qualities of the *Cabbage* and *Borecole*. It is as hardy as a Cabbage, which it resembles, but encloses a *Broccoli* head, and has the rich flavour of *Cauliflower* and *Sakato*.

This description Mr. Gilbert has never denied, and I understand he authorised it originally.—J. S. W.

KITCHEN GARDEN NOTES.

CAULIFLOWERS.—Slight showers of rain induced us to have another turn at planting out Cauliflowers, the plants now put out being spring-sown, raised in heat, and grown on in a cold pit. The sorts are Early Dwarf Erfurt and Early London. Both are of high quality and do not grow too large, and therefore we plant them as near together as 2 feet by $\frac{1}{2}$ feet. They are planted in deep drills between rows of Peas, this half shaded position favouring a rapid succulent growth, without which mild-flavoured heads cannot be had. The plants lifted with plenty of soil adhering, as a great part of it was leaf soil, consequently planting had to be done with trowels, after which they were given a good watering, and now they show but slight signs of having been transplanted. The next planting of the same varieties will take place a fortnight hence, and will very shortly be followed by a first planting of Veitch's Autumn Giant, no other variety being grown for autumn and early winter use.

RUNNER AND DWARF FRENCH BEANS.—We have made a first sowing of runner Beans, a single row through one of the principal and deepest trenched plots in the garden. The shallow trench way of growing them is that preferred, because it allows the rain to descend direct to the roots, and admits of the ready application of manurial mulchings when drought seems imminent. Though we use tall-stakes, believing that to be the most profitable way of growing them, yet, by way of inducing them to develop a branching habit, the points are pinched out as soon as the growths are from 2 feet to 3 feet long, and the process is repeated twice or thrice before they reach the top of the stakes. By this plan a greater quantity and a much longer succession of tender pods are assured, simply because the check of pinching delays the production of pods. A second sowing of dwarf Beans has also been made on a warm sunny bank, the variety being Canadian Wonder, and which is truly a wonder in regard to productiveness, as it also is in vigorous constitution

We keep the rows a yard apart and by way of making the most use of the ground, we sow between the lines early Radishes, which will be cleared off before the Beans need the whole space. Small brushwood sticks, which are used to support them, are placed in position when the plants are about a foot high.

PEAS. Main-crop sowings have been made this week, the kinds being Telegraph, Champion of England, Duchess of Edinburgh, No Plus Ultra, and several seedlings for trial. The rows range from 6 feet to 10 feet apart, and between each row is a central line either of Spinach, Lettuce, Cauliflower, or Radish. Earthing up we strongly object to, for the reason that rain cannot reach the roots nearest the base of the stems; therefore we always sow in shallow trenches, and the only earthing they ever get never exceeds the ordinary ground level, and this renders the mulching of long manure that in dry weather we always strive to apply a ready conductor directly to the roots of whatever rainfall there may be. Second early sowings are all of them ready for staking, and this we hope to do in a very few days. As usual, sparrows and chaffinches started their work of destruction by eating out the young points. Dustings of soot and lime in a general way keep them at bay, but a better way is the plan adopted by Mr. Gilbert of dusting the rows with Tobacco powder; one dose is quite sufficient; our first sowings were given but one dressing, and it has sufficed to disgust the delinquents and preserve our Peas from harm.

TOMATOES AND VEGETABLE MARROWS.—Our first batch of the former has set a fine lot of fruit, and for a time all further flower-spikes will be kept picked off to give the fruit a better chance of swelling. When this fruit is about half grown other shows will be allowed to fruit, and so on (with the earliest plants) throughout the summer. The second or main batch of plants will be left more to themselves, or, in other words, be allowed to set whatever fruit may show, and this in due time will be thinned out to the best-formed examples. If given plenty of light and free ventilation they will bear any amount of heat. Our first lot of plants occupies space in a Muscat vinery, and they seem to relish the same high temperature that Muscat Vines enjoy. The plants for open-air planting are being gradually hardened off, as we hope to plant them out by the middle of May. Vegetable Marrows are now in 5-inch pots, and are kept steadily growing on in frames and are well aired, as they must be transferred to their summer ridges early next month. We have no handlights to spare, or they would be planted out at once. No matter what the character of the weather may be when the plants are first turned out, a thick wall formed of evergreen boughs will surround each plant.

WAITING FOR RAIN.—Harsh, drying north-easterly winds are so continuous that nothing as yet grows kindly, and rain was never more ardently longed for. We have done all that can be done by way of aiding growth, such as hoeing between any rows of seedlings that have appeared above ground. Spinach and Lettuce are also ready for thinning out, but the work is impossible in the present condition of the ground. Onions, Cauliflowers, and Cabbage that were planted out a week or two ago showed such signs of distress, that, much against our will, watering has had to be done, for the slight showers we have had seem to have done them no good. We began to dig out trenches for Celery, but the soil being so dry could not be fixed in position, and, therefore, that work also waits; as does the planting out of Globe Artichokes and Asparagus.

W. W.

SHORT NOTE.—KITCHEN.

New Potatoes.—The *Cornishman* of last week contained the following interesting note: "Potatoes, grown under glass, have been drawn from time to time for a month past. The 'good old' price of 2s. 6d. a lb. was given for the first few monthals, but rapidly dropped, and, within the last week, Potatoes of good quality have been sold in Penzance for 8d. a lb. It is said on this side of the water that Scilly will begin to draw in a few days from its most sheltered bits of Potato ground. Frosts, more particularly those of Friday and Monday mornings, have again cut or checked

many acres of Potatoes in West Cornwall. That of Friday was seen to have left its blighting mark on many a plant on the western cliffs."

FLOWER GARDEN.

THE ROCK GARDEN, BROXBOURNE.

A VISIT to Messrs. Paul's nursery at Broxbourne is a practical lesson in the culture of alpine. No trouble is spared in studying their needs and preferences as to soil and position, and even the kinds of stone most likely to suit them. Stones so placed as to supply an almost vertical position for plants in the chinks between them, damp and shady spots and some parts damp but unshaded, and banks of earth where plants can find an unlimited root room; these and other varieties of treatment give many a miffy alpine a good chance of success, and most of these requisites are possible even on the smallest scale wherever the culture of alpine is attempted. The undulating rock garden, with its little dell, miniature waterfall, and sunny banks seems to have been made on a flat piece of ground with no special natural advantages of position such as may be found in or near many a country garden. Yet the result is a singular success as regards the culture of rock plants.

Perhaps at no season of the year is this collection in greater beauty than in May and early in June. But this year a visit even early in March was full of interest, though but few flowers could dare to blossom early during so cold and late a season. *Saxifraga Burseriana* major had, however, braved the weather; it flowered almost a month earlier than the type. *S. Frédérici Augusti* was a week earlier than *S. sancta*, and amongst other rare *Saxifragas* grown here is *S. cochleata* minor, with much smaller and more glaucous foliage than the typical form; it grows well in light sandstone *débris*. Much the same light soil with the addition of limestone rubbish suits *S. lanuginosa*, which should face due south. *S. Rocheliana* sometimes blossoms earlier than *S. Burseriana*; it is not a difficult kind to grow well, at least as treated at Broxbourne. The curious little *S. Rudolphiana* is like a very minute form of *S. oppositifolia*.

Coptis trifoliata, with its bright gold-coloured roots and miniature Hellebore-like blossoms about half an inch across, is grown here, and the still rarer *Coptis brachypetala* with a larger and more divided leaf and a spike of white starry flowers; neither species being, however, in blossom at the time of my visit this year. It would be interesting to know the reason in the life-history of this Goldthread (*Coptis trifoliata*) for so exceptionally bright a colour in its roots. *Ramondia pyrenaica* grows well in shade facing due north; *Omphalodes Luciliae* is also grown in shade and in loose soil. The dark blue *Edraianthus serpyllifolius* is, on the contrary, grown in a sunny position in well-drained, light peaty soil, and amongst plants which prefer limestone soil as well as sunshine, and, if possible, a situation due south, are *Oxytropis pyrenaica*, *O. campestris*, and *Androsace sarmatensis*. *Hypericum Coris* is hardy on a southern slope, and *Adonis vernalis* prefers a western aspect. A few hints as to position might be a useful addition to the directions as to soil given for each plant in Messrs. Paul's catalogue. The soil used on the southern slopes of the rock garden for about 1 foot deep is sand and leaf mould. This can, of course, be varied for plants requiring special treatment—the sweet-scented white *Daphne Blagayana*, for instance, requiring peat, though liking an elevated position.

Where *Dryas octopetala* refuses to establish itself easily, it may be of use to give it a start in rich soil, as is done here. Another good suggestion in plant culture is the planting of *Tropeolum polyphyllum* and *Crocus speciosus* in the same spot for successional flowering. *Cyclamens*, which are largely grown, are found to do well under the partial shade of Elms. For *C. cilicium*, a mixture of limestone, leaf-mould, and loam is used. *C. coum* and *C. Atkinsi* were amongst the earliest of spring flowers, and amongst others of special interest or beauty were *Anemone blanda* var. *Ingrami*, with blossoms of deep blue; *Crocus dalmaticus*, pale lilac inside, the outer segments feathered with deep purple; *Colchicum crociflorum*, like a small white *Crocus*, with pale purple stripes; and *Bulbocodium ruthenicum*, with smaller and paler flowers than the type. Some rare Snowdrops were also in bloom, and one of the prettiest winter effects in this rare collection was that of the red-brown hairy stems of *Rubus phoenicolasius* drooping gracefully over the steep side of the miniature dell.

C. M. OWEN.

***Primula obtusifolia Gammieana*.**—Plants of this lovely Indian Primrose were recently shown by Mr. Douglas at the Regent's Park exhibition. It is a native of Sikkim, at about 15,000 feet elevation, where it luxuriates upon sunny banks. The flowers are purplish crimson, becoming deeper towards the eye, where it is tinged with yellow. It may possibly be a useful form in the hands of the hybridiser. G.

Jonquils. Nothing in the way of bulbous plants grown in pots has here given so much satisfaction as the Jonquils. They flower freely, are sweet-scented, and are alike useful as plants for house decoration or in a cut state. For filling vases used in connection with their own foliage, or for mixing with other flowers for bouquets, they are very useful. They are easily grown in 3-inch pots, and thus rendered suitable for many positions where larger pots cannot be used. Three bulbs can be grown in each pot by potting them in moderately rich soil in September, and a second batch in October for succession, and plunging the pots in coal ashes or Cocoa-nut fibre refuse until plenty of roots are formed, then introducing a few into gentle heat as required. Retain the remainder in cool quarters, and allow them to come into flower during the month of March, at which time their sweet perfume is much appreciated.—E. M.

***Spiraea palmata*.**—Though this beautiful species of *Spiraea* cannot be had in flower so early in the season as the well-known *S. japonica*, yet it may be had in bloom by this time of the year, and when in this stage is a very ornamental object for greenhouse or conservatory decoration. For forcing, only those clumps with good, solid, well-ripened crowns should be chosen, and it must be borne in mind that, like all the other members of the genus, this *Spiraea* needs an ample supply of water. The plants when growing must be well exposed to the light, otherwise the flower-stems get weak and the foliage acquires a yellowish tinge, while if they are shaded just as the blossoms are developing they come out very pale, and are not to be compared to the rich hue of those grown in full light. The white-flowered variety sent out a couple of years ago by Messrs. Veitch should also become a popular favourite, for it is well suited as a companion plant to the older kind, and though the blooms are of the same colour as *S. japonica*, the two differ so widely in other matters and are both so beautiful, that the merits of either will not be discounted by the near resemblance between them. Though *S. palmata* is perfectly hardy (as the quantities that are grown at Bagshot will testify), it suffers at times in many places from late spring frosts, but when it escapes, few more ornamental perennials are to be seen. In planting out this *Spiraea* its moisture-loving qualities should be borne in mind. The best plants for forcing are those that have been grown on for

the purpose under liberal treatment, as in this way the large plump crowns are produced.—T.

MIXED BORDERS IN SPRING.

IT has become a generally accepted theory that there should be very little, if any, bare earth visible in mixed borders. In the height of the summer and autumn displays it is easy enough to put this theory into practice; indeed, the difficulty at those times is to repress undue fulness. But it is by no means so easy in spring, when the larger herbaceous plants are at a minimum of leafage. It is true that borders then can be exceedingly attractive to plant-lovers with many chaste beautiful forms, from one to other of which the eye flits, even as do the bees in the sunshine of the early year. But still the fact remains that the eye has to perform this flitting process, and the flight is across small Saharas of earth, white and dry in an east wind and a brilliant sun. The individual figures in the picture are perfect, but the picture, as a whole, is not effective.

Now there are two ways in which a remedy for this is sought, and neither of these can be approved. The first is that which fills the border with purely spring-blooming plants and bulbs, which are removed when out of bloom. Of course, when planted sufficiently thick there is no bare earth; but neither is there a mixed border, in the usual acceptance of the term; there is only a modification—and not for the better—of the ordinary bedding out. The second mode of solving the difficulty consists in filling up the intervals, or, rather, interstices, between the larger-growing herbaceous plants with choice spring-blooming plants and bulbs, and leaving them there to shift for themselves in the struggle for existence as best they may. The result in most cases it is not difficult to predict. It is simply cruelty to plants.

There is, however, a third method by which the character of mixed borders is preserved: the earth is wholly covered, and no harm is done to valuable plants. The writer saw recently an excellent example of this at St. Ann's, Clontarf, near Dublin, the residence of Lord Ardilaun. In planting a long border with permanent herbaceous plants, there were left numerous irregularly shaped spaces, which had been filled thickly with the ordinary spring bulbs and plants—a mass of blue Hyacinths, for instance, filling its own space, and throwing its arms half round a mass of the double Day Lily, bending its young leaves over, as if approving the advances of its lowlier neighbour; or Violets and Polyanthus of distinct colour overflowed the limits of their patch of ground, and traced rivulets of brightness between large clumps of the taller herbaceous plants, which later on will meet in happy embrace. Choice Daffodils have not been massed, because they are too valuable to be disturbed when they have done their work. They were in clumps, and added much to the present picture, while they will neither interfere or be interfered with by the transformation scene of summer and autumn. The ordinary spring bulbs and plants will, of course, be lifted, and the spaces filled in with the choicest annuals according to height, with single and Pompon Dahlias, and other half-hardy or tender plants.

It seems easy enough to make such a border; and yet it requires no small amount of taste and forethought to do it well: for the herbaceous plants, which constitute the bulk of the occupants, being permanent, have to be planted with a view to the spring and summer occupants, so as not to overpower the one, or consort badly with the others in height or colour. But it can be done when the same care is used as Lady Ardilaun used in forming the border in question.

The very edge of this border contributes in no small degree to its interest, if not to its brilliancy. A border of large stones, from 2 feet to 3 feet in length, is laid irregularly by the gravel walk. This forms a dwarf retaining wall for a bed of choicest alpine plants in good clumps; while another row of large stones keeps up the mixed border itself. The chinks between these two rows of stones afford

the happiest quarters for Saxifrages, Sedums, dwarf Campanulas, and many other charming plants, which would have no chance if brought into direct contact with their robust neighbours. Thus this border is a kind of epitome of all the styles of gardening—the mixed herbaceous, the bedding, and the alpine—and is pleasing and interesting in all three. F.

Claytonia virginica.—In THE GARDEN (p. 368) "K." says that this is a much neglected plant, and ought to adorn many out-of-the-way and unsightly places in our grounds. Allow me to protest that I have never been guilty of neglecting *C. virginica*; on the other hand, it has neglected me; being one of many pretty North American plants to which I have given every indulgence I can devise in the way of soil and situation, and yet none of them will make themselves a happy home here in Cheshire. May I ask where out of North America *C. virginica* can be seen growing in the wild way suggested by "K."? It is a rare plant in English nurseries, and though I have imported it several times from America, it dies out or seems to live a miserable life. Other plants from the same country which behave alike are *Mitchella repens*, *Thalictrum anemonoides*, *Epigaea repens*, *Houstonia carulea*, &c. By *C. virginica* I mean *Botanical Magazine*, tab. 911. It might be thought that "K.'s" description suits rather *C. sibirica* (*Botanical Magazine*, tab. 2243), a plant I introduced into my garden about ten years ago, and have been trying in vain to get rid of ever since, but *C. sibirica* is a native of North-eastern Asia, not of North-western America. —C. WOLLEY DOD, *Edge Hall, Malpas*.

Planting bulbs after forcing.—Where a good display of bulbous plants, consisting of Hyacinths, Tulips, Narcissi, and Jonquils, are grown yearly for conservatory decoration, a corresponding display may be obtained at this season of the year in the herbaceous borders, Rose beds, or on the Grass, if the bulbs are planted out after being forced into flower or have flowered naturally. In the front of herbaceous borders and in what was formerly an orchard we have had an unusually fine show this year. So far the spikes of Hyacinths are larger and more perfect in form than hitherto; the flowers of the Tulips and Narcissi promise to be superior to those of other years, judging by the foliage and flower-spikes now springing up. How much better is it to utilise the bulbs in this manner than destroy them, as is sometimes done. As soon as the flowers of those grown in pots are withered we cut off the spikes, give the soil a good soaking, and plant out at once. The quantity of good soil in which the bulbs grew while in the pots answers for several years to assist growth when planted out in soil of a poor character. If they are planted on the Grass indiscriminately wherever a vacant spot can be found, a pleasant sight rewards the planter in the course of a few years.—M.

Petunias in the open.—We are now putting our seedlings of these in small pots, and this reminds me of the disparaging words "Cambrian" used lately about them in a recent issue of THE GARDEN. Here, on the contrary, we consider them very useful in every way. We use for summer decoration over 1000 of them. These are all planted at the foot of a wall 3 feet high, which supports all our numerous lean-to houses in front. The aspect is due south, and in such places, when properly tied to the lattice-work of the wall, single Petunias are simply splendid. I admit that these flowers are flimsy and do not like rain, but this is not of much consequence, because as soon as the sun shines they are up again. Their loose, trailing habit renders them very valuable for clothing vases in the garden, and, like many other flowers, they ought to be used in the right place. We obtained last year from the *Parc de la Tête d'Or* at Lyons a very nice variety called *Etoile de Lyon*, in which the bright purple colour was beautifully star-like disposed on a white ground. The flowers were not large, but produced in great quantities. Some parts of our walls are clothed with the old and nice *Calystegia pubescens*, but this does not flower freely late in the season. For

the last twenty years we have tried different kinds of trailing and flowering plants for covering the walls, but Petunias still remain the best.—J. SALLIER, *St. Germain en Laye*.

GALANTHUS GLOBOSUS.

THE Galanthus figured below was obtained from Asia Minor, and has been provisionally named *globosus*, from its very marked globular form. Caught before the sun has caused the petals to expand, it is an absolute sphere. It is probably a very near relative of *Elwesi*, but grown beside 1000 *Elwesi* its form is very distinct, the outer segments being a little shorter and much broader than in *Elwesi*; in *Elwesi* they are shaped like a gravy spoon, in *globosus* like a soup ladle. Another peculiarity of it is that it so constantly produces two flowers from one spathe without fasciation. I have only six bulbs of it, and of these four gave twin blossoms. The inner segments are deeply blotched with dark green, fan-shaped at the base, as in *Elwesi*, but always being clearly and distinctly arched at

Galanthus globosus. Engraved for THE GARDEN from a photograph by Miss Jekyll.

the edge; whereas the general form of *Elwesi* has two nearly square patches at the corners unconnected by the span of the arch, and even when the span is present it is comparatively faint compared with that of *globosus*, which is deep and sharp and clearly defined. It is an extremely pleasing variety, and very robust. The bulbs, like the flowers, are almost perfectly round, and the foliage is somewhat broader than in the general run of *Elwesi*. W. WILKS.

Shichen Vicarage, Croydon.

Anemone nemorosa. We have rarely seen so many *Anemone nemorosa* in the forest as there are this year. For some miles the underwood of the great Oaks along the beautiful *Terrasse de St. Germain*, so well known to tourists, is one white carpet, as the flowers are so densely crowded. These *Anemones*, perhaps more than any other flowers, are subject to movement. In the morning with the first rays of the sun they open their corollas, which were

closed during the night, and then they gradually turn during the day, keeping time with their bright companion, looking eastward at sunrise and westward at sunset. March and April have been cold and dry; this perhaps accounts for the profusion of blooms and their lateness. Amongst these wild flowers peeps here and there the *Bouton d'Or* (*Golden Button*), as we call the *Ficaria verna* here; in other places also may be seen *Pulsatilla officinalis*, with its bright blue flowers; *Primula officinalis*, much sought after by children; Violets, &c. The soil is so dry that the delicious *Morchella esculenta*, though generally plentiful at this season, seems very rare this year, as we have only found a few dozens of very small ones.—J. SALLIER, *St. Germain en Laye*.

NOTES FROM YORKSHIRE.

MARCH has been a destructive month here. At the end of February rather tender plants had suffered no damage. *Cyclamen coum* was out in flower at the foot of an Oak tree, *Garrya* and *Jasminum multiflorum* were in full beauty, and *Eucorcarpus* had shoots several inches in length. The very cold weather which prevailed during March, principally from the 11th to the 25th, was the real winter. The severe cold at night, coupled with cloudless skies and hot sunshine from the 12th to the 18th, did great damage to shrubs. Some plants of *Biota orientalis* 7 feet to 8 feet high, which have passed unharmed through eight preceding winters, are completely killed. *Pinus insignis* will, I fear, follow them. The various *Cupressus* (*orientalis*, *macrocarpa*, *Lambertiana*, &c.) are much injured, but a young plant of *C. Corneyana* remains unharmed. The *Fitzroya*, *Sequoia sempervirens variegata*, *Sciadopitys*, *Arthrotaxis*, and *Cryptomerias* remain unharmed.

The cold March seems to have suited the bulbs. I have never seen the *Erythroniums*, *Scillas*, *Chionodoxas* (both *Lucilie* and *sardensis*) finer than they have been this April. Is *Chionodoxa sardensis* at all an improvement on *C. Lucilie*? Is it not rather a poor form of that plant? Daffodils began to bloom outside April 1, the first being *pallidus precox*, from the Pyrenees, and trumpet minor, No. 25 of Hartland's catalogue. These were shortly followed by *Ard-Righ*, our own English *pseudonarcissus*, *obvallaris*, and the so-called *spurius* forms. *Gemms* came next, and now the Grass banks are aglow with flowers of *Horsfieldi* and a Pyrenean form nearly allied to it, as also *Emperor*, *Empress*, both of which, as also *Ard-Righ*, I consider superior to *Sir Watkin*, which is in bloom near them. The incomparabilis and odorus groups are opening, to be followed very soon by *Tazetta*, from near Cannes, and all the lovely forms of poeticus from Lachen, Albano, &c.

As with the bulbs, so with the alpine Primulas; I never saw *nivalis* more perfect than it has been this month. *Vivipara*, from the Pyrenees, and various Swiss forms, including the true yellow *Auricula* from the Eggischhorn, have made the alpine rockwork gay. *P. rosea* has been covered with bloom, *denticulata* likewise, and I see *P. sikkimensis* is starting. *Soldanella alpina* and *Gentiana verna* are in bloom. How fond the mice are of the latter! I have difficulty in preserving it from their ravages. *Saxifraga Burscheriana* proves itself to be a perfect gem, flowering throughout the intensity of March frosts, and it was almost rivalled by the lovely *S. sancta*, in bloom at the same time. *Saxifraga Fortunei* and *ciliata* have stood the winter unharmed.

R. MILNE-REDHEAD.

Holden Clough, Clitheroe.

Doubling of hardy Primroses.—In reference to this matter touched upon by "A. D." on p. 367, I may state that I have just received a letter from the Hon. and Rev. J. T. Euseawen, in which he tells me that he "found a double yellow Primrose in the midst of the common yellow in a wood miles from any garden. I should think that no double yellow had ever been grown within ten miles of the place I found it. It was, no doubt, a seedling."

from experiments carried out here the leaves appear to be just as good when the flowers are allowed to open as they are if the blooms are removed.—H. P.

SEASONABLE WORK IN PLANT HOUSES.

GREENHOUSE. STOPPING YOUNG HARD-WOODED STOCK.—Much of the future appearance of the specimens depends on due attention to stopping the shoots during the early stages of growth. If this is not attended to soon enough so as to induce them to branch out sufficiently to furnish the base, nothing that can be afterwards done will correct the mischief. But to do the work without regard to the habit natural to each particular kind of plant is a mistake; some things, such as *Aphelaxis*, *Tremandras*, *Dracophyllums*, *Erioste-mons*, *Hedaronas*, and *Pimeleas*, when once the shoots are fairly balanced, the plants usually branch out sufficiently of their own accord without further stopping. Whereas, such species as *Choro-zeumas*, *Acacias*, *Boroniads*, *Polygalas*, *Hoveas*, *Leschenaultias*, *Metrosideros*, and *Pleromas*, are always liable until they get old to produce some shoots much stronger than the others, and if these are not stopped in time they monopolise so much of the sap, that the weaker branches languish and ultimately make little progress. In addition to timely pinching out of the points of the over-strong shoots as they appear, it is well to tie them well out in a horizontal position, leaving the weaker growth more erect; in this way the heads will be more evenly balanced.

HEATHS. The difference that exists naturally in the habit of growth in the different varieties of Heaths is such that some forethought requires to be exercised in stopping the shoots. The erect-habited varieties of *ventricosa*, *Cavendishi*, *ferruginea*, *propendens*, and the *vestita* sections need more or less attention for several years after the plants have reached the ordinary trade size; whilst such kinds as *ventricosa coccinea minor*, the *tricolors*, *retorta major*, the different varieties of *ampullacea*, *gemula*, *Rhyana*, *Austiniana*, and a host of other bushy growing sorts, when a proper foundation is laid, no more is required to preserve well-balanced heads. As to the best time for potting Heaths there are different opinions; for young stock I prefer getting the work done before hot weather comes on; in the case of such as have attained specimen size early enough in autumn so as to admit of the roots getting well hold of the soil before winter is the best. My own experience is that there are fewer large Heaths die after repotting at the time named than when they are shifted late in spring or summer.

WITSENIA CORYMBOSA.—This fine old blue-flowered plant, though its blossoms are individually less conspicuous than those of some other greenhouse subjects, yet as it blooms at the latter end of the year and affords a colour that is not over-plentiful, it is acceptable to those who are not willing to confine their cultivation to the ordinary things met with. The plant is easily managed and not liable to get out of condition, continuing in a healthy state for a long time. It is a slow grower, and to this cause not unlikely may be attributed its seldom being seen. Young plants take several years to grow them up to an effective size; consequently those who purpose growing them will find it better to secure well-established examples that have made a few seasons' growth. Though, as already said, this *Witsenia* increases in size slowly, it is still a free rooter, and must not be under-potted; if this occurs progress will be checked. Where there are any doubts as to the roots requiring more space, it is well about this time to turn the plants out of the pots to ascertain their condition in this respect; if this is done carefully there need be no disturbance of the ball, so that in the event of additional room not being needed the plants can be replaced in the pots they have hitherto occupied. Good fibrous peat mixed with a moderate amount of sand suits this plant. Pot firm, and in the case of small stock that are required to attain size without delay a little closer atmosphere than most greenhouse plants require will be an advantage. Syringe

overhead each afternoon during the growing season, giving plenty of light with air in accordance with the state of the weather.

SWAINSONIAS.—There are two or three sorts of these handsome Pea-flowered plants that are deserving of cultivation. They are comparatively quick growers that when once fairly established soon attain enough size to be effective. Young plants that are now in 6-inch or 7-inch pots should be moved to others two or three sizes larger; they will thrive in either loam or peat, yet the latter if of good quality is preferable. Mix a fair amount of sand with the soil and pot moderately firm. These *Swainsonias* require frequent stopping until moderate sized specimens are secured, without which their natural habit of growth is such that they run up with a limited number of shoots. Full-grown specimens that were cut back after they had done flowering last summer will now have made considerable progress, and when grown as trained plants must have their shoots trained round the sticks intended for their support. Old plants of this description need not be re-potted every year, as by the use of manure water given at short intervals until they are nearly in flower, or by surface dressings of concentrated manure that will get washed down to the roots in watering, they may be kept in a sufficiently vigorous state. These plants are somewhat liable to the attacks of red spider; a regular use of the syringe will prevent this insect gaining a footing. *Swainsonias* make good pillar plants either when turned out in a bed or grown in pots; when so used less stopping is required whilst they are young. When grown in this way, especially if the roots are confined in pots, they must be well nourished either with manure water or with the surface dressings already mentioned. *S. galegifolia*, *S. galegifolia alba*, *S. Osborni*, and *S. Rollissoni* are good sorts.

ORANGES.—One of the characteristics common to the different varieties of Citrus is their ability to exist in some fashion under usage that would speedily end in death to most kinds of plants. Very often they have to struggle through the growing season with a much lower temperature than they like, and when the house in which they are located is such as to admit of their receiving a fair amount of light and the soil is sweet and of fair quality, and the drainage of the pots or tubs is efficient, the plants keep in fair health. But when they can have an intermediate temperature, especially during the time their growth is being made, it is much better. When large old specimens get out of health the growth made is thin and weak, the leaves coming small and pale in colour. When in this state it is well to turn them out of the pots or tubs and get away as much of the old soil as can be done without too much interference with the limited amount of healthy fibres that usually under such conditions exist, putting them in smaller pots or tubs in good, sweet soil, with enough sand in it to render it porous. If possible a gentle bottom-heat should be given, continuing it until the young wood is nearly matured. The atmosphere should be kept moderately moist, giving shade in bright weather and syringing overhead at the time of closing the house in the afternoon. Under treatment such as this, continued for two seasons and giving proportionately more warmth in winter, much may be done to restore the plants to their wonted health. Unhealthy Oranges are often much affected with scale, which, like most other parasites, attacks plants more persistently when they are in bad health. Means should be taken to rid the plants of these pests, which will increase apace with the extra warmth they receive.

CORREAS.—These distinct-looking plants are useful for conservatory decoration, and from the fact of their being much more easily managed than many other hard-wooded kinds, they might with advantage be more generally grown. Although moderately free rooters, they can be kept in a thriving state in smaller pots than many things of a permanent character. The best time to repot either young stock or larger examples is in spring. Though they will thrive in either peat or loam, the former is prefer-

able where the texture is such as will enable it to last well.

STOVE.—DRACENAS.—The different species and varieties of these plants that require warm treatment can be propagated in several ways. Most of the kinds form a thick fleshy root, or rather continuation of the stem, from which proceed the smaller feeding fibres that support the plant; this underground stem keeps descending until it reaches the bottom of the pot, where its downward progress is stopped; yet it still continues to grow, the effect of which is that the ball of earth is often lifted up above the rim of the pot. In the case of sorts that are scarce and that it is desirable to increase, young plants can easily be secured by taking off about 2 inches of the fleshy root described, with the fibres attached, putting them bottom upwards in small pots, just covering the ends. In a brisk, growing temperature they will soon make growth and produce leaves. In this manner additional plants can be obtained each spring at the time the old specimens are potted, as after the ends have been severed, the stumps soon begin to descend again. When old examples of *Dracena* get bare at the bottom they become unsightly, and it is best to head them down; the present is a good time to deal with any that require it. The extreme top if taken off with three or four leaves attached will soon root if treated in the ordinary way for cuttings. The lower part of the stem may be cut into pieces from 1 inch to 3 inches long, according to the character of growth natural to the particular sort. Each bit should have one or more eyes to it. These stem cuttings should be inserted 2 inches apart in a pot or pan in sand. In the course of eight or ten weeks they will have formed roots and made sufficient top growth to admit of being potted off singly. Another method of propagating *Dracenas* is to shake the soil away from the roots, cut off all the leaves and the extreme top, and then lay the stem, with its roots attached, down in a propagating box, covering the whole slightly with a mixture of fine peat and sand, keeping the material moderately moist, with plenty of heat. Treated in this way, the eyes will push into growth, and when they have made three or four small leaves each they must be severed from the old stem and potted singly. Any remaining eyes on the stem that have not moved will then make growth, and can in due time be taken off and potted. T. B.

GARDEN FLORA.

PLATE 594.

TUFTED PANSIES.

(WITH PLATE OF PANSIES *ABERCORN GEM* AND *MRS. KINNEAR*.)

WE adopt this name to avoid the confusion arising from giving the name *Viola*, the name of the genus, to a particular race of Pansies that are really raised from the common Pansy crossed with one of the alpine *Violas*. They were given the name of "*Viola*" to distinguish them from the ordinary Pansy, but giving the name of the genus *Viola* to one set of varieties leads to confusion and much questioning. Their habit is a little more tufted, they endure the winter better, and usually grow more closely than Pansies do; therefore, a good name for them would be tufted Pansies. They are beautiful things, growing freely, and flowering for a long time, and have pretty and delicately coloured flowers.

The Scotch nurserymen do these well, and in Scotland they are seen to greater perfection, owing to the cool air and long days. We prefer to move them every year, as they seem to do better by frequent removals; many of them when well grown are as large as Pansies, and, we think, more beautiful. Apart from their intrinsic beauty, they have value to people who

* DRAWN FOR THE GARDEN at Gravetye Manor, Sussex, by A. G. Moon, August 6, 1886, and printed by G. Severeys.

go beyond the garden for their types of beauty, for the self-coloured kinds admirably typify the pretty alpine Violas, which few of us ever see in their native pastures. We obtained these two kinds from Messrs. Dicksons, of Edinburgh. It is desirable that people who grow these flowers should make a selection of their own, and grow some of the beautiful selfs, as nurserymen are apt to pick out spotted and bizarre forms, and overlook delicacy of colour. It would be worth while to raise seeds too, so that one might select one's own colours in these flowers. Some of the prettiest kinds we know are scarcely in the trade, and were not raised in nurseries. The variety of lovely colour is so great, that the most fastidious would have little trouble in raising and increasing shades of colour they liked. We think this would be worth doing in many cases. It would help to add an individual charm to gardens. The two kinds we figure are very beautiful—the white, a most precious flower, superior, we think, to any Pansy we have tried in the flower garden, spreading freely into soft green tufts, and bearing bold flowers of a fine creamy white. The plants as drawn grew on deep loamy soil, and were planted at the end of April.

Lims for Cyclamens.—With reference to Mr. Wilson's note on this subject in THE GARDEN, March 26 (p. 272), I may mention that I once had a similar experience with some plants of *C. persicum*. I annually grow some on the easy plan of planting them out in cold frames in April, lifting and re-potting about the last week in September. Our ground is very full of worms, and one year they worked into the compost in which the Cyclamens were planted in great numbers. They were doing much damage, by coming up in the night eating off the tender young leaves just as they issued from the bulbs. I tried lime water, but it only drove them down for a time, as I could not sufficiently flood the soil to kill them for fear of making it sour. I then lifted them carefully and mixed a quantity of lime with the compost. I put so much in, that the soil was quite coloured, and I thought that I had probably overdone it, but there were no evil effects. On the contrary, I never saw foliage have better substance. This seems to prove that lime is of especial benefit to Cyclamens of all kinds. The addition of some to the compost when giving the last shift would, probably, be beneficial, especially in the case of loams that are naturally deficient in this respect. Watering with lime-water when the pots get full of roots I know does good. I fancy that the use of lime is not so fully understood as it should be. In the case of many hardy flowers I believe that a dressing of lime would make a great difference in their growth.—J. C. B.

Effects of frost on spring flowers.—Having read the remarks of "R. D." and "D. T. F." in THE GARDEN (p. 368) on the effects of the frost upon *Myosotis dissitiflora* and *Omphalodes verna*, I find that here, where *Myosotis dissitiflora* is planted out annually by the thousand, it has withstood the severe frosts better than any other bedding plant that we have; whereas great numbers of Pansies and Daisies have perished. Wallflowers have also suffered severely by the frost. Although some of the Wallflowers were not planted until late in the autumn, they have not withstood the frosts better than those planted five weeks earlier. In a bed fully exposed to the north and north-east we have planted *Chionodoxa Lucilia*, with a groundwork of *Myosotis*; the *Chionodoxa* was planted two years ago, and was only just peeping through the ground the last day in March, thus showing what a cold position it is in; and at the present time the *Myosotis* is one mass of flower. The severe frost that we had from March 13 to March 30 did more damage to the spring bedding than the whole of the frosts during the winter months. I have been watching with some curiosity the growth of some Daffodils growing round a pond here. Some of them have been covered to the depth of 2 inches

with water during the whole of the winter months, and only within the last fortnight has the water gone down to its usual level, yet the Daffodils sprang up through the water quite as early, and flowered as profusely as those growing higher up the bank in quite a dry position. Have any of the readers of THE GARDEN observed anything of a similar nature? F. H. L. Belton.

FERNS.

W. H. GOWER.

CHEILANTHES ARGENTEA.

THIS plant is a native of Siberia, Kamtschatka, Japan, and Khasya. In the latter place it is found growing at elevations varying from 3000 feet to 5000 feet. Our illustration was taken from a plant gathered in the neighbourhood of Yokohama, in Japan. It appears to have been introduced to cultivation as long ago as 1823. It is a most elegant plant, of tufted growth, not exceeding 4 inches in height and 2 inches in breadth. The footstalks are jet black, the upper side of the fronds bright green, the under side densely clothed with silvery white farinose powder, ornamented with a marginal line of black sori. This plant should be grown in a small pot, with good drainage and free open soil, composed of loam and peat, with pieces of sandstone intermixed. It should be liberally supplied with water to the roots, but the fronds must not be sprinkled with the

Cheilanthes argentea. Engraved for THE GARDEN from Nature.

syringe. It luxuriates in a cool fernery shaded from the sun.

C. chrysophylla is a similar plant to the preceding, but differs in having somewhat longer fronds, and these have a dense coating of golden yellow farina on the under side. It grows in Khasya at the same elevations as *argentea*.

C. Borsigiana, also known by the name of *Nothoekena sulphurea*, is a somewhat similar plant, but its fronds are more lobed; they are bright green on the upper side, clothed with light yellowish golden farina beneath, and should be potted in similar material to the others and treated in the same manner. It requires a warm house, being a native of Tropical America.

The Killarney Fern as a town plant.—As a reader of THE GARDEN, I may be permitted to give my experience of growing this Fern in London, though only an amateur. About sixteen years ago I had a case made, in shape something like a large cage. It was eight-sided, and had a wooden tray 6 in. deep, lined with zinc, on which rested eight glass sides, 18 inches high; two of these sides could be removed at will. The diameter of the case was 2 feet. I filled the bottom, first, with inverted flower-pots, then with broken crocks and charcoal,

lastly with good peat, mixed with bits of tufa and charcoal about the size of Apples, and raised it gradually until the centre was 6 inches or 7 inches above the edges of the tray, and watered it to make all firm. On the top I planted my Fern—a small, but strong plant of *Trichomanes radicans*, carefully pegging down the tawny brown rhizomes. It succeeded admirably, and in about two years my case was full of the loveliest green fronds. I never watered it unless some of the fronds appeared dry, and then only sprinkled it. It never had any air unless when being watered because of our burning gas in the room, yet it fruited very well. The case stood at a window which the sun did not reach, and was turned round a little every day (by a special contrivance) that the light might reach it evenly. I had it for twelve years in London, and it was the loveliest ornament in the drawing-room. During those years the soil was only once renewed. I quite agree with "R. D.'s" opinion that enthusiasm and attention are the main elements of success.—M. M., Haunts.

THE NEPHROLEPIS.

THESE handsome and very distinct Ferns on account of the graceful appearance of many of them, as also by reason of the many ways in which they may be effectively used, occupy amongst our decorative plants of all descriptions a most prominent place. All the varieties of *Nephrolepis* may safely be said to be of very easy growth, forming in a comparatively short time, especially when planted out in the fernery, some large and imposing masses of light and elegant foliage, hardly equalled, and certainly not surpassed, by any other Ferns. Some species are particularly adapted for the decoration of the warm house, while certain kinds thrive equally well under much colder treatment. Among these, the most useful are *N. tuberosa* and *N. exaltata*, the value of which may be seen in the numbers that are to be found in our flower markets. *N. tuberosa*, although an East Indian species, is the hardiest of the two, and its habit, which is more bushy than that of *N. exaltata*, recommends it. Its fronds are narrow, of a dark green colour, and seldom exceed 2 feet long. It has also a peculiarity which few other kinds possess of producing little tubers on the roots. *N. exaltata*, as its name implies, is a much stronger grower, its fronds frequently attaining from 3 feet to 4 feet in length; they are about 3 inches broad, and of a pleasing light green colour. Both kinds are evergreen, even when kept all the year round in the cool house, and both are particularly well adapted for planting on rocks or boulders near the water or under larger growing Ferns. The majority of the *Nephrolepis*, however, require stove treatment, at least during the winter, and certain sorts all the year round. Among the kinds of medium growth the most striking is undoubtedly *N. Duffii*, a species as beautiful as it is distinct; a native of Duke of York's Island, in the South Pacific Ocean. Its fronds, which vary from 15 inches to 20 inches long, are densely crowded, pinnate, and much crested. The pinnae, instead of being narrow as in most other species, are small, produced in pairs, and of variable shape, most of them being semi-circular, and all deeply toothed. The compact, elegant habit of this Fern, and its bright, pleasing colour, with the agreeable vase-like shape which it assumes when fully developed, combine to make it one of our most attractive kinds. It is also excellent for room decoration, if a little care is taken in hardening it off previous to its being used.

N. pectinata, although an old acquaintance, is not grown so extensively as it really deserves. It is a South American species whose fronds, dense and comparatively narrow, seldom exceed 15 inches in length. They are produced in profusion and form a very compact mass of most pleasing bright green colour. In *N. Bausei*, of garden origin, we have one of the most distinct and handsome of its kind among those of medium growth. Although a form of *N. pluma*, its habit is totally different, being dwarf and bushy, with fronds averaging about 15 inches in length. These, as in the species from which it originated, are of a particularly light green colour and of a somewhat thin texture, but they differ

from all other known kinds by their pinnae being pinnatifid instead of entire, as is the case with all others belonging to the same genus. It also partakes of the deciduous and tuberous characters peculiar to the species from which it springs, and its foliage generally lasts from April to December. During the resting season care must be taken that the soil does not get too dry, as then there would be a great danger of the tubers, which form the most ready means of propagation, shrivelling up. *N. philippinensis* is another pretty kind with medium growth; the fronds narrow, erect, and of a beautiful dark green colour. The strong-growing section supplies us with plants eminently fitted for the roof-decoration of the warm house, where, when grown in hanging baskets, they show themselves to perfection. Most of these are natives of Java and the Malayan Archipelago. The old *N. davallioides*, through the graceful habit of its growth and the handsome appearance of its fertile fronds, which attain, when grown in a favourable position, the length of 5 feet, is a species of no ordinary merit. The fertile portion of the foliage, which is limited to the upper third part only of each mature frond, is very peculiar and attractive, inasmuch as while the barren pinnae are only about 3 inches long, the fertile ones, which frequently attain 5 inches long, are very narrow, contracted, and gracefully drooping. We have in *N. davallioides* fereans a variety of robust growth, which, both in habit and general appearance, is a great improvement on the normal form, from which it differs in the furcation of the pinnae. In the barren ones, which are few in number, at the base of the fronds the furcation is less conspicuous, and in some cases only rudimentary; but in the fertile ones, which occupy the greater portion of the frond, the furcation is twice, and even three times repeated in the extremities of the first division, becoming more complex towards the apex of the frond, where it forms a massive crest. It also greatly differs from the species by its mode of growth, sending forth, as it always does as from a central tuft, numerous arching fronds from 3 feet to 4 feet long, and of a very bright and glossy nature.

Nephrolepis pluma, a native of Madagascar, is a beautiful drooping deciduous Fern, with light and very slender fronds, reaching about 5 feet in length and about 1 inch in breadth in all their parts. These fronds, which have on each side from eighty to 100 pinnae, are of so pendulous a nature, that a strong plant with its numerous plume-like fronds forms a most elegant object when grown in a basket suspended from the roof of the warm house. It is leafless, or nearly so, from December to March, during which time, however, it requires to be kept moderately moist at the roots. There are also *N. acuta*, *falciformis*, *hirsutula*, *ensifolia*, and others, which are all more or less grown; but the most distinct, and also the most beautiful, of all the gigantic growing kinds is undoubtedly the new *N. rufescens tripinnatifida*, a native of Fiji, whose fronds, which reach 3 feet or 4 feet in length, are of a lovely light green colour, and possess a peculiarly massive, yet plumose appearance, produced by the broad pinnae being regularly and constantly tripinnatifid, their margin being on both sides deeply cleft and covering each other in a most graceful and effective manner. Unfortunately, like nearly all plumose forms of species of Ferns already in cultivation, this is, or until now has proved entirely sterile; but being provided with the wiry running rhizomes peculiar to its genus, this new *Nephrolepis* is easily propagated by the same method as that employed for commoner kinds which produce young plants on their rhizomes at intervals. On planting them in the fernery, either warm or cool, a certain allowance must be made for the rapidity of their growth, as also for their spreading propensity, for if planted too near small growing kinds these will inevitably in a short time be smothered by the *Nephrolepis*. The *Nephrolepis*, although not very fastidious as regards the soil in which they grow, at all times prefer a compost of a very open nature, and nothing suits them better than a mixture of fibrous peat and Sphagnum Moss in about equal proportions, with an additional part of silver sand, and for the strong growing kinds a

little fibrous loam. In that compost, as in partially decayed vegetable matter, they produce in abundance their wiry rhizomes on which the crop of foliage is dependent. These rhizomes, besides their usefulness in procuring a ready means of propagation, constitute also one of the principal ornaments of the majority of the species, especially when these are grown in brackets on a wall or in hanging baskets, in which they form most attractive objects. *Nephrolepis* require plenty of moisture at the roots. This must not on any account be overlooked, as if allowed to get dry, even for a very short time, the pinnae, which are articulated, drop off suddenly, leaving only unsightly and bare stems on the plants, which greatly suffer in consequence, and require a long time of generous treatment to recover their former vigour.

S.

FRUIT GARDEN.

W. COLEMAN.

HARDY FIGS.

It will be interesting, nay more, highly instructive, to learn from non-protectors how their open-air trees have passed through this protracted winter. If the embryo fruit as well as the young wood is safe and the trees give promise of one good crop of Figs, this year of Jubilee will be a most fitting period for giving up protection and all such fussy and untidy contrivances, as I question if this now general favourite fruit has passed through such a trying spring since Cardinal Pole laboured for its extended cultivation. It will, however, I am afraid, be the same old tale so often repeated—the majority crippled, the few spared to bear fruit in the autumn. It is, of course, possible to carry protection too far, but this is no argument against its judicious use, as we find hobbyists in every department riding their favourite steeds until they drop. The same remarks apply to non-protectors, who, because once in a week's march they find a poverty-stricken tree in a dry, sunny corner braving all weathers and bearing fruit, arrive at the conclusion that thatching or matting should be dispensed with. I recollect many years ago an old friend waiting upon a gentleman in Warwickshire with a view to completing an engagement as gardener. On their way round the fruit garden the baronet said he grew excellent Figs without the useless trouble of protection. Not liking the looks of the trees—it was then late in the spring—my friend stepped up to them, and on his return remarked that it would have been better had he taken that trouble, as all of them were dead. Here, no doubt the pitcher had gone many times to the well, but received the fatal blow at last. The same thing happened at Arundel and other places in famed Sussex a few years ago, and will be repeated in less favoured parts of the country so long as Figs are grown. I have just uncovered my trees, and, judging from their appearance, believe they have plenty of living points well furnished with embryo fruit. Pruning will be deferred until they get more advanced, as we are quite a month later than we were at this time last year, when, provided they turn out satisfactorily, their food will be the reverse of rich, but they will have plenty of it, and ripe wood will be secured by thin training upon bricks from which the sun is not entirely excluded. Possibly I may be told by "W.," whose jeremiad at p. 365 I have just read, that Fig growing must be given up, as we can get them cheaper from Smyrna, but the price, low as it may be, will be an addition to the English gardener's wages. Therefore, whilst admitting the truth of some of his remarks, I cannot endorse his views, as I

am of the opinion that able men having the charge of large gardens should devote their energy to the production of all kinds of fruit and vegetables, whether from a market grower's point of view they are profitable or not. Whether they are necessities or luxuries, surely the more a man grows the better his services will be appreciated.

FRUIT PROSPECTS.

We have seldom had a better or more promising show than this year. Almost unprecedentedly late, the trees are exceptionally vigorous and crowded with healthy blossom, and as we have now reached the 20th of April it may be hoped that the blossom is almost through the danger period. Peaches, Apricots, and Plums on walls are now in full bloom. Pears and Plums in the open have scarcely moved, and Apples are still more dormant. Cherries are also late, and as well clothed with bloom as the others. This promises to be a great Plum year. I have seldom seen Plums on or off walls more thoroughly whitened over with bloom, or closely packed with blossom-buds. Apples also promise an extraordinary crop, and Pears a full average.

Gooseberries and Currants are also well furnished, and have passed through the long cold winter with but little bud-picking where care was taken to destroy bud-eating birds. The latter also threatened the Plums so much, that they had to be almost extirpated to save the Plums.

Raspberries have also passed through the winter well. We thinned out the fruiting and superfluous current year's canes as early as possible, and have reaped the benefit of the full exposure of those left, in their perfect hardness and unusual strength.

Strawberries here have mostly lost all their old leaves, but the crowns do not seem greatly injured, though experience proves that the crops are seldom quite so good when the plants are denuded of all their old leaves in the winter or early spring. I have found a dressing of soot a good reviver for plants thus defoliated, as well as a capital and sure exterminator of slugs, snails, or other such pests that hug the crowns more closely and devour them more ravenously in the absence of the old leaves.

A slight sprinkling of guano is also helpful to Strawberries under such conditions. It is certain that the sooner a new head of leaves is formed the better for the size and flavour of the current year's crops. D. T. F.

The best time to mulch.—The best time for mulching is of considerable importance, for, as a rule, it is too late in being put on. Many never think of assisting the development of the wood and fruit of their plants by mulching or top-dressing until it has attained a large size and is nearly matured; then it is applied unstintingly with the object of finishing off the crop; but mulchings and surfacings at this late period are useless, and if they are to be beneficial they must be put on at the time the fruit is beginning to swell. No trees pay more handsomely for mulching than those growing against walls, such as Peaches, Plums, Apricots, Cherries, &c., and as these crops are now forming, I would strongly advise their owners or cultivators to mulch at once with good manure, and both the trees and the fruit will soon show its application. I have generally noticed that mulched trees suffer less from insects and blight than unmulched ones, and the plan of mulching ought to be reduced to a system everywhere.—CAMBRIAN.

Planting Strawberries.—In forming new Strawberry plantations, gardeners often put out young runners late in autumn. This is about the worst method that can be followed. Even if good strong runners are selected, they cannot get good root-hold by winter if the planting is delayed until the middle of October. The ground, by reason of the previous preparation, being in a more or less loose state, is sure to be brought into a close condition by the heavy rains of winter. Moreover, the plants, however firmly they may be set in the ground, inevitably become loosened by the action of

frost. After hard winters, when severe frosts have alternated with periods of mild weather, I have known autumn-planted runners to be worked almost out of the ground. When this occurs, and harsh drying winds, such as we have lately experienced, set in, unless prompt remedial measures are taken, the plants are sure to suffer. They should be looked over, and any that may be displaced pressed into the ground again; at the same time the soil around them should be well trodden down. When new plantations cannot be made in summer, so that the plants get well established by winter, it is better to defer the planting until early spring. The runners may be pricked in thickly together for the winter, but I prefer to let them remain where they have rooted. If the ground is laid up roughly early in March for a week or two, and then well broken and the manure forked in, it will remain in a free condition all through the season, and on soils of a tenacious nature the plants will make better progress than when set out in autumn. It is only when the natural staple is of a very light description that autumn-planting is preferable. Such soils dry up very quickly in spring and early summer, so that plants put out at these seasons of the year are apt to suffer in their earlier stages of growth, unless looked to well in the matter of watering. All light soils before planting should be well trodden or rolled, and a mulch of manure is of great service. — *The Field*.

MEALY BUG ON VINES.

ALL experienced Grape growers have a natural dread of stocking their Vines with mealy bug, but after all that can be said about it, there are yet worse and more common pests to contend with. For instance, I would rather have to manage or clean bug-infested Vines than to have charge of a vineyard where red spider invariably effects a lodgment on the foliage. The mealy bug can be kept under, if not actually destroyed, and any way, if they can be kept out of the bunches not much harm is done. At any rate, it does not effectually stop the proper colouring of the berries, and this cannot be said of the red spider so common to many modern structures. Where so many thousands of short-lived summer-bedding plants have of necessity to be propagated, the vineries as well as nearly all the other houses have to be crowded for a time with various plants. Among these *Besines* and *Colenses* figure largely, and if there are any mealy bug on the place they will be found on one or both of them. From the bedding plants to the Vines is only a short distance for the comparatively active bug to travel, and they are liable to become well established before they are observed. This is no imaginary solution of the difficulty of accounting for their presence, and the overworked gardener must not receive all the blame. Either fewer tender bedding plants should be grown or there should be proper facilities for their preparation provided. What, however, we are most concerned about is not how they came on the Vines, but

HOW TO GET RID OF THE BUG. — In *THE GARDEN* (p. 365) a correspondent, "C. T.," condemns gas-tar as a winter dressing, and ventures to predict it will never come into general use. In this and in other respects I am confident he is much wide of the mark. Six years ago I took charge of an old bug-infested vineyard, and a friend strongly advised me to dress the rods with a mixture of equal portions of gas-tar and clayey water, and this advice I followed, the two ingredients well stirred together being of a consistency of thin paint. The rods were not closely skinned, only quite the loosest bark being removed, but they were well scrubbed with hot soapy water, the house also being thoroughly cleansed and the walls whitewashed. The tar mixture was applied cold with home-made matting brushes, and keeping it well stirred prevented the clay from separating from the tar. No attempt was made to fill all the crevices, neither is it necessary, the mixture effectually closing them up. I do not assert that one dressing of this "wretched" compound completely clears all the bug from the Vines; on the contrary, neither this nor the dressing recommended by "C. T.," viz., Gishurst

compound, will accomplish it, but I do say it is the least liable to injure the Vines. The dressing of the rods by the tar or any other mixture must be supplemented by close attention in the spring and early summer months. If the Vines are looked over frequently and what few bugs show themselves destroyed, a complete clearance will be effected. The time taken up in this almost daily search is scarcely worth mentioning, but if it is neglected the bug soon regains an ascendancy, as anything in the shape of one dressing powerful enough to kill them also damages the Vines. We had a few bugs on our Vines the second season, but these being caught in time they did no harm, and not one was found the following year. Last year a quantity of *Besines* were thoughtlessly placed along the front of the house, and from these the Vines were stocked once more. They were well hunted for, and the tar remedy has apparently nearly cleared them out again. As to the tar

INSAURING THE VINES, I must say it has never occurred here, nor would any injury befall them elsewhere if the mixture was intelligently applied. Nothing but tar and clayey water are needed, and if the former does not preponderate, or is not allowed to accumulate on the surface of the jar or pan containing the mixture, there is no fear of its interfering with the growth of the Vines. The spurs and buds may be completely coated over with it, and yet they will break strongly and may be safely tied down. If I might hazard an opinion I should say "C. T.," in common with many other cultivators, is in too great a hurry to tie down the laterals, and in this case many of them are liable to be drawn out of the sockets. This is especially the case with those that are started late and are naturally very strong. Black Alicante, at times, will scarcely bear touching, even syringing over-head being liable to cause some of the laterals to break away. Where they can be left, it is advisable not to tie them down in any way till they have flowered, after which they will stand comparatively rough treatment. The shy setters, such as Muscat of Alexandria and Mrs. Pine, flower more strongly when not tied down, the bunches of bloom getting much more light when the laterals are nearly upright, and all the others set and do well under this treatment. In the majority of vineries the rods are trained much too close to the glass to admit of the laterals being left so long untied, but this may be obviated by dropping, or suspending, the rods much lower than usual. They may be brought up to the wires again all in good time. If this plan cannot be adopted, then the laterals must be very gradually brought down, taking care not to strain them to any extent, as only a jar may cause them to fall off. It is a critical job and must be done with very great care, and if tar really made matters worse I can quite understand anyone ceasing to use it. I ought, perhaps, to add we annually dress Vines in four houses with the clay and tar mixture, bug or no bug, and this season I cannot find the least trace of any injury to the laterals from its use. Paraffin or, properly speaking, petroleum, on the other hand, is a dangerous remedy to resort to. Many rods have in various gardens been completely ruined by it as a winter dressing, while isolated bug in the summer may be easily killed without it. W. J. M.

Peach trees casting their fruit buds.

"A. M.," page 364, says, "Can any of your readers state the cause of my Peach trees dropping their fruit buds? They have been planted twelve months last autumn and grew well last summer; they are in a border 18 inches wide and 1 foot deep, at the back of a lean-to vineyard. When the buds should have begun to swell they all turned brown at the base and fell off." The old story. Peach trees planted in a border of the above dimensions under extraordinary management might be induced to produce perfect flowers and fruit, but the chances would be heavily against them. Like many more, you have allowed your shallow borders to get dry through the winter and did not restore them to a growing condition before the trees were started this spring. But why confine them to 12 inches of soil when double that depth is not too much? and why

plant them beneath the shade of Vines, as though any dark, dry, spiderly place were good enough for a Peach, when, as all fruit growers know, these natives of the East rejoice in bright sunshine, plenty of light, and fresh air? Having lost the season, all that you can do may be summed up in a few words: increase the width and mulch well the surface of the border; never let it get dry winter or summer, and pay proper attention to the training of the young wood. Meantime, study the pages of *THE GARDEN*, where you will find the fullest information down to the most trifling details upon the management of this or any other fruit. Had you been a careful reader this disappointment might have been avoided. W. COLEMAN.

THE PRODUCER AND CONSUMER.*

THIS essay on fruit and vegetable growing, and the economic distribution of farm produce, is dedicated to the Worshipful Company of Fruiteers, and published by Mr. J. L. Allday, Edmund Street, Birmingham. The author's first idea was to circulate it privately among growers with whom he is acquainted; but noblemen and gentlemen to whom it was submitted in manuscript advised that it should be published, and Mr. Rawson specially acknowledges the unremitting kindness and help received from Sir J. E. Eardley Wilmot and Sir Edmund Leechmere, M.P. He advances the great fact that England imports produce, other than corn, of the annual value of fifty millions sterling, and urges that, by altered conditions (to include revision and reduction of railway rates), the greater part of this money might be kept in the country for the general benefit and the special advantage of British agriculture. As a fruiterer and salesman of thirty years' standing, he unselfishly proposes that the agency of middlemen should be dispensed with. He indicates the kinds of fruit, vegetables, and flowers which sell best; maintains that poultry farming may be profitably developed; recommends bee-keeping (steps being taken to prevent the traffic in so-called honey, which is nothing but glucose-sugar syrup made from starch); and then deals with the important question of distribution. He thinks there is but one way of dealing with the produce with the most advantage to the seller and to the immediate benefit of consumers generally, and that is by a combination of the landowners, farmers, market gardeners, fruit and vegetable growers, agricultural labourers, and all classes interested, to form companies or societies properly organised and carried on in large centres, to provide for the reception and sale of produce. He believes that a trade of this kind to the extent of £150,000 a year might be done in Birmingham. In connection with a central depot there might be ten shops for doing retail business; and the company should also possess a factory for making jam and marmalade where all suitable fruit unsold might be taken at a price to pay the grower, instead of being disposed of at an unremunerative price in the market. Fruit syrups and other things in good demand might also be made for home consumption and export. Mr. Rawson does not adopt the notion of establishing jam factories in fruit-growing centres. He thinks they should be placed in large market towns so as to serve for the surrounding district and to provide ready means of distribution to consumers. A company might also assist small farmers and other growers whose credit is not considerable, and might hire trucks to enable small sellers to send their produce cheaply. Further, Mr. Rawson states his views as to railway rates and agricultural education. On all subjects of which he treats he writes plainly and concisely. His style is that of a practical man, who knows what he has to say and says it shortly and clearly. Birmingham politicians have often talked of what should, in their view, be done for the land. Mr. Rawson is not a political theorist. He may not intimately know all the difficulties and all the work of the farmer; but he is a man of business who has been closely connected with practical men, and as he writes with considerable knowledge and with unmis-

* "The Producer and Consumer." By Samuel Rawson, Small Heath, Birmingham.

takable sincerity, his essay is well worth reading.—From *Berron's Worcester Herald*.

Grape Bidwill's Seedling.—This Grape is not much grown now, owing to its having received a bad character, which, in my opinion, it does not deserve, as I am satisfied from inquiries I have made during the past four years that there are two Grapes which have been grown under the same name. I have seen and tasted both. One of them I allow is of really bad quality as compared with a Black Hamburgh, and the other very little inferior to that well-known sort. The latter, I have been assured by a gardener who has grown and shown it for several years, is the true Bidwill's Seedling. A west country gardener told me that he had shown it in the Black Hamburgh classes, and obtained prizes with it in a strong competition. The bunches, never large, even on vigorous Vines, are short and thick, and as they always colour well (while the spurious sort does not) they have a striking resemblance to the Black Hamburgh, but when seen growing side by side Bidwill's Seedling is quite distinct from it. The original plant from which the stock was obtained was in existence three years ago in the neighbourhood of Exeter.—J. C. C.

SEASONABLE WORK AMONG FRUITS.

ALTHOUGH this is one of the latest seasons on record, severe frosts and keen north-east winds having prevailed up to the end of the closing month, fruit prospects are fairly satisfactory, and, provided the long-delayed improvement is permanent, the realisation may yet exceed our hopes. This, however, is just one of those peculiar reasons which throws the oldest observers off their guard, if not out of their reckoning, as we often find the most promising-looking trees casting their flowers wholesale, from the fact that the long-retarded sap as well as the frost has proved too much for them. A very short time, however, will now set this anxious and important matter at rest, and whether our crops are abundant or light, those who have left no stone unturned in the way of preparation of the trees and protection of the blossoms will have least reason for regret. When trees are properly prepared they endure the severest winters, and often carry full crops of fruit after passing through the most inclement springs; whilst others not so prepared, although pictures of promise up to the flowering stage, with wind and weather in their favour, become infertile and unprofitable, with the result that some of the finest varieties are obliged to bear in silence the blame which should fall elsewhere. Preparation, then, being quite as important as protection, fruit growers this spring who have kept the two points in view will most likely have the best crops of fruit to compensate them for their attention.

APRICOOTS, which have been so long in a semi-flowering state, are not likely to be good; but, comparatively speaking, these are of much less value than Peaches and can be better spared. Still, so long as Apricots are grown, they should receive the most minute attention to every detail, or be given up. Here I do not think them worth the good south walls upon which Peaches do so well, and have therefore transferred them to a west aspect, where their early flowers escape many sharp frosts, and, what is equally disastrous, bright sun striking them before they are thawed and dry.

PEACHES, as I observed some time ago, are this year better with us than I ever saw them, and, judging from present appearances, thinning will be no sinecure. The trees, too, are perfectly clean, no small matter after three weeks' exposure to a dry, scorching east wind. Disbudding in ordinary seasons might now be commenced; but after so many checks and delays, this operation will be postponed until the trees have thoroughly recovered their power, and warm nights, the best of all guides, justify our removal of the superfluous shoots. Many people disbud every part of a tree at one and the same time; but when it is borne in mind that the strongest tree can be reduced to a state of weakness by the simple pro-

cess of pinching off a portion of its leaves, few will attempt to gainsay the statement that the process should be performed piecemeal and with the greatest caution. The first step, in which none can go wrong, is the stopping of gross shoots, which, as a matter of course, emanate from gross and not infrequently half-ripened wood of the preceding year. These may be checked before they have time to rob the weaker parts of the trees; but, as I have just observed, if well prepared for fruiting these gross shoots should never have been allowed to exist, as pinching and re-pinching force the superfluous sap into other and weaker channels. Once the balance of a tree is secured, it is better to be a little behind than a little too forward in the general disbudding, as it is pitiful to see a fine tree suddenly stripped, its fruit and limbs exposed to frost, and its leaves attacked by insects and blister. In our most favoured counties disbudding may be performed by a mechanic, or it may go by default, and the trees grow and fruit freely for a time; but a bad season settles them, simply because the careless hands that allowed them to go wrong cannot give the attention necessary to their restoration. In cold districts, where every ray of sunshine must be turned to account, disbudding, like root-pruning, is one of our most important operations, and for this reason it must be followed up until every bare stem and bit of wall is covered with foliage, hanging from shoots which cannot overlap nor become crowded during the summer. Indeed, where this work is well done, autumn pruning becomes a very light business; the shoots, just enough and none to spare, get thoroughly ripe; insects are not allowed to exist, and Peach-growing is profitable and pleasing. The Peach-grower must ever be on the watch for insects. Although clean to-day, the trees may be attacked to-morrow; therefore, with the sap in a backward and languid state of circulation, not an hour must be allowed to pass unoccupied in making preparations for their destruction. Insecticides are numerous, but all are not alike applicable, especially when the trees are in flower, as many washes are quite as fatal as the insects to the tender organs of fructification. Once set, the usual dips and washes may be applied; but here two points must be observed—the washes must be weak, and their application on the appearance of a frosty night must be avoided. This, at least, is my experience, as embryo fruits are very tender and often suffer from the two causes combined. This season I intend making my Peach trees distasteful to fly, by running over them every week with Bloxham's excellent little fumigator. The plan has answered economically and well under glass, and I have arrived at the conclusion that rendering trees insect-proof, either by the use of smoke or bitter washes, is often better than awaiting the approach of the enemy.

PEARS AND CHERRIES are masses of flower, and promise well, as may readily be supposed, when the lightness of last year's crops is taken into consideration. Plums, on the other hand, are thin, and in many places will require quite two years to recover from the strain of the enormous crops they bore last year. Then, to make matters worse, the bullfinches have preyed upon the buds to an extent rarely experienced in the annals of fruit culture.

GOOSEBERRIES from the same causes are in similar plight, and unless they recuperate beyond expectation our trees will not give pecks where last year they gave bushels.

CURRANTS look better, and Raspberries having ripened their canes to the top are sure to be good. If these were not heavily mulched in the autumn they will now require a copious supply of water through the hose, when more light, rich manure may be cast round the stools or along the sides of the rows. The Raspberry sends a few strong roots into the subsoil, but all the most useful feeders run a few inches below the surface, where, the winter having been comparatively rainless, nothing short of heavy mulching, combined with plenty of water, can possibly secure a full crop of luscious fruit. Because the Raspberry belongs to the humble bush fruit section, many people, if they do not exactly neglect, certainly do not give it the best attention

within their power, and yet I question if nine-tenths of the owners of good gardens would not give up their Pines, and Melons, and Grapes in preference to parting with their bush fruits. Quite right too, for independently of the fact that bush fruits, green, ripe, or preserved, form one of our most wholesome articles of daily consumption, one might challenge the English gardener to produce a fruit that in point of flavour will beat a first-rate Raspberry or Gooseberry. Unfortunately, in one sense, birds, having been deprived of their natural enemies, now have time and strength to play sad havoc with their friends' property, and we are put to the expense of converting our gardens into sundry aviaries, with this difference—the birds are allowed to look on, but not assist in harvesting the crops. This protection we have always given to Strawberries, Raspberries, Currants, and Cherries, and now we are preparing to enclose the blocks of Gooseberries in fine wire netting. Some of the breadths of wire must be movable for letting in insect-destroying birds at certain seasons, otherwise caterpillars innumerable will soon average this coercive step by devouring every green leaf, and one may as well be without fruit as without leaves.

APPLES generally are looking well and flower-buds are abundant, but late, so that with a sudden change to growing weather we may find the wood-buds taking the lead. The only point in their favour is well-ripened wood, for had this been defective our orchards would certainly have been in full leaf before opening their flowers. What we now want is a plentiful fall of warm rain to soak the dry bark and buds of the trees, to cleanse them from the larvae of insects, and penetrate to the lowest roots. The ground in this part of England is unusually dry, and unless we have a repetition of the heavy falls experienced last May, when miles of the country were flooded, fruit trees of all kinds must suffer, if not when setting, certainly before they mature their crops of fruit. Already all our wall-tree borders have been twice watered, and this week another inch will be given them. The craze for concrete bottoms and a filter-bed of rubble 12 inches or more in depth has not proved an un-mixed benefit, especially where provision has not been made for a frequent deluge in dry weather. By all means let us prevent the cold spring water from rising by the use of concrete, and let us prevent an excessive rainfall from hanging in the subsoil to become cold, sour, and injurious, but we must bear in mind that there is reason in all things; and if we plant our fruit trees in light borders resting on heavy drainage, we must tank up our rain water in wet weather for setting at liberty when long periods of drought prevail. With the exception of watering, mulching, staking, and tying, the work in this department will be light for some time to come; but one matter it is not yet too late to put to the test, and that is the thinning of the buds of Apples on Paradise and Pears on Quince stocks.

We have just finished grafting, and although rain is wanted, a dry spring is not unfavourable to the roots of recently beheaded stocks. W. C.

Apples as ornamental trees.—I wish some of your readers who have considered this question would let us know the kinds of Apple which form the largest and most picturesque trees when full grown. I am not now thinking of their quality as fruit at all, but if they happen to be good kinds as well as handsome, all the better. There is no tree so beautiful as the Apple, and I believe many people would plant it for the sake of its beauty if they knew the kinds that make the finest trees. Beauty of bloom should be a consideration as well as size and form of tree.—W. R. R.

SHORT NOTE.—FRUIT.

Best manure for pot plants.—As a stimulant and food four components "W. M." should use guano, either Peruvian or ichthemic; the latter is preferable for pot plants. Next in merit is sulphate of ammonia. Nitrate is a dangerous manure to use, and constitutes a stimulant only.—REX.

ORCHIDS.

W. H. GOWER.

PROMENEAES.

THIS genus includes a small and natural group of Brazilian Orchids, the members of which are dwarf and compact in habit of growth. Some few years ago these plants were more frequently to be found in our plant stoves than is the case at the present time, the desire for novelty having apparently caused them to be neglected. They do not long remain in a healthy condition when their roots are surrounded with much soil, and for this reason they are admirably adapted for cultivation upon blocks of wood or in small, shallow suspended baskets. During their growing season they enjoy an abundance of water to their roots, if it can pass away quickly, and also daily sprinklings overhead from the syringe. This,

of deep purple, the thick, fleshy lip being deep blackish purple. *P. citrina* has rich, deep yellow flowers, the lip bearing a blotch of deep crimson at the base, whilst the inside of the side lobes is spotted with the same colour. In *P. micropetra* the flowers are creamy white, except a few lines and spots of purple and crimson at the base of the lip.

Cymbidium tigrinum—This is a dwarf growing and very handsome member of this now popular family, originally discovered by the Rev. C. Parish growing upon rocks in the Tenasserim Mountains of Burmah, at an elevation of some 6000 feet. It was introduced to Messrs. Low's nursery at Clapton in 1863, and was figured the following year in the *Botanical Magazine*, t. 5457, but has always remained very rare. The pseudo-bulbs are roundish-ovate; the oblong lanceolate leaves are leathery in texture, from 4 inches to 6 inches long and bright green; flowers large and spreading; sepals and petals yellowish

Promenea Rollissoni.

however, must be discontinued when the plants are in flower. Treated in this manner and subjected to good light, with the temperature of a Cattleya or intermediate house, they flower freely and form very attractive objects during the autumn months. A very pretty effect can be produced with these Promeneas by grouping two or more species in the same basket, as they are tolerably uniform in size, and bloom about the same time, thus intermingling flowers of different colours and affording an agreeable contrast. The following are a few of the best kinds: *P. Rollissoni* (represented natural size in the annexed cut) is about the largest of all the species. In this plant the sepals and petals are soft golden yellow, the side lobes of the lip being stained and spotted with crimson, and the column streaked with bright red. In *P. stapelioides* the sepals and petals are greenish yellow, thickly spotted and barred with transverse lines

green faintly dotted with red; lip large, middle lobe white marked with numerous short transverse lines of dark purple; side lobes erect, inner side purple with a faint tinge of yellow. We recently noted a fine specimen of this handsome species bearing sixteen flowers in the nurseries of Messrs. Shuttleworth & Carder, Clapton Park, where it has been grown in the cool end of an intermediate house. —G.

Cypripediums at Clapton—These plants are grown in very large quantities by Messrs. Low. Nearly all the kinds are kept in a warm, moist atmosphere, which, judging by their vigorous growth and their floriferousness, suits them admirably. At the present time some 2000 flowers of *C. Lawrenceanum* may be seen, some fully expanded and others ready to open. The bold, handsome flowers and brilliant, marbled leaves render this the showiest kind in the barbatum section. *C. ciliolare*, introduced from the Indian Islands, is another very handsome plant, and is at the present time bearing

hundreds of its beautiful flowers. The plant appears to be somewhat intermediate between *C. Argus* and *C. superbiens*, *C. bavigatum* and *C. Lowianum*, two other distinct and handsome Slipper Orchids, are now very beautiful. —G.

Odontoglossum polyxanthum.—This plant resembles *O. Halli* in its habit of growth. It produces a spike upwards of 2 feet in length, the individual blooms measuring upwards of 4 inches across. The sepals and petals are deep tawny or bronzy yellow, blotched with numerous chestnut-red markings; lip chocolate-brown edged with white, fringed round the edge with tooth-like spines. It is one of M. Kluboeh's discoveries, and still continues rare. We recently saw it flowering at The Woodlands, Streatham, where it is grown with such kinds as *O. coplatum* and *O. Pescatorei*. —G.

Vanda teres. Mr. Roberts, of Gannery Park, has adopted a plan of growing this Orchid by which it flowers in the most profuse manner. The plan is to plant it out in a frame, heated underneath by hot-water pipes, on which are placed about 4 inches of corks, which are covered with about the same depth of Sphagnum Moss. In this compost the plants are placed and slightly shaded for a few days. After they begin to form roots the shading material is entirely dispensed with, and they are allowed to grow in the blazing sun. This treatment seems to suit them admirably, as they were growing and flowering very freely, the spikes bearing on an average from six to eight flowers. We should add that the plants in question have not received any water since last August until they began to develop their flower-spikes. —W. T.

Cattleya intermedia.—The typical *C. intermedia* produces long, stem-like pseudo-bulbs, 2 feet or more in length, and is somewhat straggling in habit when compared with those of the labiata section. It is exceedingly useful, however, for blooming during the month of April, just when the beauties of *C. Trianae* are on the wane, and before *C. Mossie*, *C. Mendeli*, and *C. Gaskelliana* open. Where this species is objected to on account of its height, a dwarf form which I recently saw in the gardens of Mr. Measures at Streatham will become a great favourite. It produces flowers as freely and as large as its taller relation, and is identical in colour, but its pseudo-bulbs are from 9 inches to 1 foot high only, so that it forms a compact and handsome mass. *C. intermedia* is one of the easiest of Cattleyas to grow, and will thrive at the cool end of the Cattleya house. —G.

Odontoglossum Halli.—I send you by today's post a box containing a spike of *Odontoglossum Halli*, which I consider very superior, and would be much obliged for your opinion on the same. I also send you a raceme of *Dendrobium thyrsoiflorum Walkerianum*—at least I bought it for that. I send you as good a truss as any on the plant, and the longest bulb of this year's growth is 2 feet 6 inches. —A. C. M.

* * * The *Odontoglossum Halli* received is a large-flowered and excellent variety; the same may also be said of the *Dendrobium thyrsoiflorum Walkerianum*. —ED.

SHORT NOTES.—ORCHIDS.

Masdevallia xanthina is a very pretty and distinct kind, which we recently saw flowering at The Woodlands, Streatham. In shape it resembles *M. Shuttleworthi*, but the flowers are somewhat more relaxed; the sepals are lemon-yellow, stained at the base with purple-black. It appears to thrive under the very coolest treatment. —G.

Odontoglossum vexillarium Cobbianum—This very distinct and handsome form is now flowering with Mr. Measures at The Woodlands, Streatham. The sepals and petals are of the same colour as the type, but the lip is pure white, which renders it very conspicuous, especially when seen side by side with the deep-coloured forms. —G.

Cœlogyne cristata—In reply to Mr. Douglas in THE GARDEN, April 16 (p. 358), the other occupants of the house in which the plants were grown, referred to by me, consisted of *Cypripediums*, *Cymbidium*s, *Odontoglossum*s, and *Masdevallias*, the minimum winter temperature being 45° to 50°. When I stated that heat was only applied in cold or dull weather, I meant during the growing season. I quite agree with Mr. Douglas that this Orchid will not succeed in a cool greenhouse. —C. R.

SEASONABLE NOTES ON ORCHIDS.

THE COOL HOUSE.—This section of Orchids has already become the most popular in some gardens, and in many instances contains the most valuable plants. The Orchids cultivated in the cool house are natives of the mountain districts of South America principally, and if we confine the occupants of this house to these plants, introducing only such other species and varieties as are known to succeed well with the same treatment, the results will be satisfactory. Those who insist upon saying that this, that, and the other Orchid will do best in a cool house, with insufficient knowledge of the subject, are much to blame. Inexperienced cultivators trust to the editors of the horticultural press to supply information upon which they can depend, and unless the cultural details given are based upon successful practice they may mislead the unwary. The introducers of new Orchids, too, have a habit of over-lauding the plants they introduce, which is natural, as they go by the descriptions of collectors, who see the plants in all their pristine beauty in their native habitats. We could excuse all this if they would also send with the plants a correct description of the position in which they were found growing, with the night and day temperatures as far as they can supply them. It would save much worry and needless expense if information of this kind was always forthcoming. I well remember trying to grow *Odontoglossum Roezli* in the cool house when it was first introduced, and after losing nearly half our plants—which cost a guinea each—the remainder were saved by placing them in the warmest house. Any *Odontoglossums* requiring repotting may now be attended to; but I may add that we have none so late in the season as May; all ours were potted in February and March. Any newly imported plants are potted at once into as small pots as the roots will go into, and they are not again repotted until the last-formed pseudo-bulbs have been matured, and the plant has once more started into growth. Some species very speedily show by their vigorous growth that they require plenty of pot-room. Such is *Maxillaria venusta*, a species that ought to be in every collection; it is a cheap Orchid, producing its beautiful, sweet-scented white flowers at mid-winter. I prefer it to *Lycaste Skinneri alba*. Small specimens in a few years grow into large, handsome masses, and it can be as easily divided as any common herbaceous plant. Another desirable winter-flowering plant is *Odontoglossum Edwardi*; it does not grow so very freely in some collections, but we have no trouble with it, treated exactly like *O. crispum*, and watered freely all the year round. *O. pardinum* is another disappointing species, but the best varieties when well grown are exceedingly showy plants. The colour of the flowers is a clear yellow. All the *Odontoglossums* requiring large supplies of water at the roots ought to be potted in good fibrous peat and Sphagnum, with plenty of potsherds mixed with them; and the pots should also be filled to half their depth with good drainage. The smaller growing species flowering at regular periods, such as *O. Rossi*, *O. Cervantesi*, *O. blandum*, *O. Ernesti*, &c., we re-pot in May, and place them near the glass roof, some of them being suspended in baskets close to the glass. This makes all the difference between success and failure sometimes. We have at the warmest end of the cool house a large group of *Masdevallias*, and among them a variety of *M. Harryana*. This particular variety did not succeed on the stage with the others; many of the young growths rotted off when they had pushed about an inch or so. A portion of the plants was suspended near the roof in Teak baskets, and these immediately improved in health—not a single growth damped off; whereas they still continue to do so on the stage. This is a simple cure for any refractory subjects that do not succeed well when placed amongst others on the stage. All the smaller species of *Masdevallias* are grown in that way, so also are the *Chimaphila* group, the latter being placed in Teak baskets for the better development of the flowers. If it is necessary to divide and re-pot any specimens at this season, break them up with the fingers in preference to using a knife. One good grower told me that *Masdevallias* failed to grow when a knife was used to

part a large specimen into smaller portions. The night temperature is now ranging between 15° and 50°, with a rise by day; with sun heat the temperature has run up to 75° with the shading down. When the temperature is high, sprinkling the paths and stages with water has an excellent effect on the health of the plants. The shading should be let down before the temperature rises to 70° in this house.

We will re-pot plants of various kinds in the Cattleya house whenever opportunity offers during the months of May and June. *Cymbidium eburneum* has now gone out of bloom, and every plant requiring re-potting will be seen to at once; we use for these and some others of this genus, good, fibrous, yellow loam, with the addition of leaf-mould and a little decayed manure. *Zygopetalum crinitum*, now growing freely, after flowering should also be re-potted in good peat and Sphagnum. Many species and varieties of *Cattleyas* may also be repotted, but not unless they really require it. Better err on the side of under than over-potting these plants. It is difficult to hit the exact requirements of *Cattleyas* as regards the quantity of water to be given to them. They must not be watered every day like the little *Platanos* suspended from the roof; even small plants do not require it oftener than twice in a week; we have large specimens which may not require water oftener than twice in a month. These remarks apply to established plants. The temperature is from 55° to 60° at night; by day, with sun heat, 80° to 85° is not too much. In fact, the plants do best with a high temperature and moist atmosphere by day, but the flowers do not last so well in it, and in order to keep up a good display we are tempted to maintain a lower temperature and drier atmosphere.

The East India house is kept about 5° higher, and a growing, moist atmosphere is maintained. The air of this house is laden with the perfume of the Rose-scented *Odontoglossum Roezli*. Summer-flowering *Cypripediums* are pushing up their flowers. We will pot during the month some of the *Angracums* and *Saccolabiums*, using Sphagnum Moss only. J. DOUGLAS.

CHRYSANTHEMUMS.

E. MOLYNEUX.

SINGLE VARIETIES.

GROWN in such a manner that the plants produce blooms in masses is the way this section shows to the best advantage. They flower profusely, the blooms lasting a long time either on the plants or in a cut state, and they do not require either so much space or so much pot room as do the larger kinds. They are extremely useful when grown to flower later than the ordinary kinds, and are well adapted for growing in a dwarf state for room decoration, or even as dinner-table plants they are appreciated by some, and the bright-coloured varieties make an agreeable change during the dull season of winter. The most effective method of cultivating them is growing the plants in bush form. Long spikes branching freely in a natural manner produce flowers in abundance, but where large individual blooms are required for exhibition—as they are when staged in bunches of three flowers of each kind—other means must be resorted to. I think the above way of staging the single varieties is not the best manner, as they are far better staged in bunches where all the flowers which grow upon each stem can be set up, thus showing how floriferous they are when properly cultivated; however, fashion decrees otherwise, the rage being all for size of individual blossoms. To have flowers in quantity the following details should be followed: Strike the cuttings in the ordinary way from the middle of January to the same time in February. When the plants are 4 inches high pinch them for the production of side branches,

shifting as required before they are at all root-bound. Keep them stocky in growth by standing the plants thinly, thus allowing a freer circulation of air amongst them, and keeping them as near the glass as possible. Remove them to cold frames as soon as circumstances will admit. Capital plants may be grown in 8-inch pots, but if extra large ones are wished for, 10-inch pots should be used. One topping is enough for some of the plants; while those required to be grown to a larger size to assist in the decoration of lofty conservatories should be topped again when the shoots are 5 inches long. Place them about the middle of May outside in an open, yet sheltered, position, and never allow them to suffer for want of water. Thoroughly syringe the foliage overhead on the evenings of fine days, thus rendering the leaves clean, and keeping them free from many kinds of insects which are apt to attack them. Whether the plants are intended for very large specimens or moderate-sized ones, the shoots resulting from the topping of the branches should be allowed to grow away at will, never thinning any out or dislodging any of the flowers, as the effect of such spikes laden with flowers must be seen to be realised. During the growing season supports of some kind should be fixed in the pots to prevent the branches from falling about. This is best done by placing in each pot three stakes in a triangular shape, attaching a piece of bast to each. This will answer well until growth is completed, when other stakes may be placed to the stems, spreading out the shoots to the best advantage. To have larger flowers suitable for exhibition stands the cuttings may be struck at the same time as advised for bush plants, but, instead of topping the plants at 4 inches high, allow them to grow with one stem uninterrupted until they break naturally into other growths. From three to five blooms on each shoot is a fair number, according to the size of the flowers of each kind. Those which are intended to produce the former number should at the first natural break be selected, rubbing out all remaining branches and subsequent growths, also the flower buds, which will again form at the point of each shoot, until the buds show which will be the best for the production of large blooms. This will take place during the end of August and the early part of September. Soil similar to that described in a previous issue should be used, and stimulants freely given when the pots are full of roots. After the central flowers are cut, others are produced by the side shoots in succession. House the plants in batches to prolong the display, and if some can be temporarily protected from frost before they are placed in the houses, the season will be much prolonged.

For the production of small plants suitable for vases, the following details should be observed. Plant old or young plants on an open space of ground; the former may be planted early in April, while the latter should not go out until about the middle of May, tying the stems firmly to stakes as they grow to prevent breakage by wind or other accident. Do not top the shoots, but allow them to grow uninterrupted; but in the case of the old plants thin the stems to six on each, and if more spring from the base remove them. Early in September when the bloom buds are forming, take off the points of the shoots about 8 inches long, inserting them in pots, five cuttings in a 4½ inch and nine in a 6 inch pot, using sandy soil with a free admixture of leaf mould, and give a good watering to settle them firmly in the soil. If the cuttings are not taken off the plants till the flower-buds attain a good size they do not root so quickly, and consequently the leaves

flag more when they are taken from the hotbed, for they require a gentle heat with shade to prevent loss of foliage. Sprinkle with tepid water every day in fine weather until they are rooted, then gradually harden off and place in a cool house as near to the glass as possible to keep them sturdy. Each plant will produce several flower-buds if the side ones are removed, retaining only the one at the extreme point of the shoot; this flower will be much larger than if all were allowed to grow.

The following varieties I find are first rate for the various purposes named: Helianthus, yellow, shaded with bronze, large flower. Crushed Strawberry is an excellent variety, having long, drooping florets of the true Japanese type. America has the largest florets of all the varieties, light pink, large, and of good form. Oriflamme, dark red, large blooms. White Perfection, as its name implies, is a pure white, medium in size, of good form. Patience, deep lilac, with fringed florets. Miss Gordon, light pink, having long, drooping, thread-like petals. The above are excellent for growing where large blooms are required for exhibition, while those named below are good for bush plant culture, producing blooms in quantity: Oscar Wilde, dull brick-red. White Perfection, Mrs. Wills, white. Mrs. Langtry—this is a gem, the colour light lilac, blooming most profusely, dwarf in habit, while the flowers have a powerful violet odour. Lady Brooke, bright yellow; small flowers of a buttercup shape. Nelly, light pink. Meteor, dark. Mrs. Dr. Duke, bluish. In addition, the above-mentioned varieties are also as good for this form of cultivation as for producing large blooms. The three kinds I will now name are the best for late flowering, lasting long after all others are over, therefore they are of much value: Elsie Maud, white, free-flowering; Miss Lulu Martin, small pink blossoms; Miss Rose, dwarf in habit, pink.

TRAINED SPECIMEN CHRYSANTHEMUMS.

THE method of growing trained specimen plants is not largely adopted for the reason that considerable space is required to house them, and much time is necessary to bring them to that state of perfection which will entitle them to the name of specimens. These trained specimens are not so useful as other styles of growth, because by removing any of the flowers from the plants their appearance is spoiled; still this way of growing Chrysanthemums finds many admirers. Exhibitions would lose much of their attractiveness if well-grown and skilfully trained plants were absent, as it often happens at some shows that the specimens are the leading features. There are two methods of producing specimens: one is growing them to a large size, say 5 feet in diameter, with 200 blooms, or sometimes more, on each plant—the plants trained in a Mushroom-like manner. The other is limiting the plants to about 3 feet in diameter, with from thirty to fifty blooms of high class merit, quality being the first consideration. Plants of the latter type are much more desirable than those grown for mere size, as the quality of the flowers must then be a secondary consideration. Medium-sized and not over-trained plants remarkable for large deep green foliage and grand blooms are the most meritorious. Plants intended for either system should at this period be furnished with from four to six stems, having been topped when 4 inches high, and again when additional branches have grown, consequent upon the pinching out of the points of the plants. The plants at this stage should have a position close to the glass in a cool house or a cold frame where a free circulation of air can be given, great care being used that they neither become pot-bound nor dry at the roots. Neglect of either at this time would cause a serious check to the plants, which might not be visible at once, but later on, a partial loss of the lower leaves would do much harm to the future

welfare of the specimens; therefore strict attention should be paid to all the details of culture, and at the proper time shift the plants into larger pots as necessary until the largest plants are in those of 12 inches in diameter, while weaker-growing kinds or those intended for the smallest class of specimens will do in pots 11 inches in diameter.

Chrysanthemums which have been planted at the base of bare walls, in order to cover them at the time and manner previously described, will now require attention in the matter of thinning out the young shoots, which generally spring from the base of old plants in numbers far in excess of what is needed. Neglect of this selection of the best stems renders all weakly by overcrowding, and where the wall is dwarf this is a serious mishap. Select four or six of the best on each plant, removing all the others.

E. M.

PROPAGATING.

JASMINES. None of the species of *Jasminum* are difficult plants to increase from cuttings, yet one or two matters require to be taken into consideration in order to ensure a reasonable measure of success in their propagation. Probably no *Jasminum* has attracted so much attention within the last few years as the beautiful sweet-scented *J. pubescens* or *gracillimum*, and this also merits note as being the easiest of them all to increase, for suckers are pushed up with considerable freedom, which may often be detached with a few roots; next, cuttings of the young shoots will strike if put in sandy soil and kept in a close case in the stove; while lastly, cuttings of the roots will grow under the same treatment. In mentioning cuttings of the young shoots I did not mean those that were still in a succulent condition, but rather just as that stage is passed, and the shoots commence to acquire a woody texture. In *Jasminum Sambac* and its double-flowered variety, the principal consideration is to select the right kind of cuttings, as if they show at all a tendency to flower, they will stand a long time without growing, even after they are rooted. Such being the case, it will be necessary to choose the growing shoots as cuttings, but they strike best if not too stout and vigorous. The same rule will apply to all the tender kinds, and regarding those that are hardy, the greatest interest is centred in the common white *Jasminum* and the beautiful golden spring-flowering *J. nudiflorum*, both of which can be increased by cuttings put in a cold frame at any time during the latter part of the summer, and kept close and shaded till rooted. Besides this, cuttings about a foot long can be inserted in a sheltered border about September. The cuttings should be buried in the ground for about three parts of their length, and the soil pressed down firmly, as a most critical ordeal for them are the drying winds of early spring. Both of these will also strike root from layers, and as their rambling habit often places a branch at disposal in a convenient position for layering, added to which larger plants can be produced than by means of cuttings, it is a method of increase that commends itself where but few plants are required.

DIPLODENIAS that have passed through the winter in a state of rest will be now in active growth, and when in that stage they may be readily propagated. The best cuttings are those formed of the growing shoots (not the most succulent, as they are liable to decay), and inserted singly in small pots. The advantage of putting such subjects in single pots is that some often take a longer time to root than others, and being each in a single pot, the rooted ones can be removed from the close case without disturbing those that have not yet reached that stage. A light soil largely composed of peat, leaf-mould, and sand is a very suitable compost for the cuttings, and before use it must be passed through a fine sieve. The pots used should be small, not more than a couple of inches in diameter, and drained by a few broken crocks, or, better still, pieces of charcoal. The pot being filled up with the above compost pressed down moderately firm, and finished off with a little pure sand on the top, is then ready for the cuttings, which should be pre-

pared by taking off just below a joint and removing the two bottom leaves. They must then be inserted up to the two next leaves, and where needful, secured to a small stake. After a thorough watering the pots must be placed in a close case in the stove, and being attended to in the matter of watering, shading, &c., can in about a fortnight be plunged in a gentle heat, when they soon root. A common error in watering cuttings when first put in is not to give them enough, for even in those that are liable to decay, a thorough watering may be given when first put in without in any way endangering the success of the operation. In the case of all cuttings by far the better way is to water them before placing them in the close propagating case, and it should be applied through a fine-rosed water-pot in such a way that not a cutting is disturbed, and yet sufficient quantity must be given to wash the sand on the top into a smooth unbroken surface.

COMBRETUM PURPUREUM.—This can be struck occasionally from cuttings of the young growing shoots, but they take a very long time to root, and failures are frequent. Such being the case, another method is usually employed for the increase of the *Combretum*, and that is by grafting portions of the branches on to pieces of the roots. In order to obtain roots large enough for stocks it will be necessary to take them from an established specimen, and, generally speaking, the best are furnished by one that has been planted out. A length of about a couple of inches is a very suitable one for the stocks, and the scion, which should be formed of a half-ripened shoot, may be fitted either in the wedge manner or by side grafting, but whichever is done great care must be taken to make the union as complete as possible, and the whole must be tied securely in position. After this they must be potted so that the point of union is below the surface of the soil, and then plunged in a gentle bottom heat in a close case, where they are to remain till a union takes place. During the interval considerable care must be exercised in watering, shading, and air giving, as the *Combretum* is in this stage rather a delicate subject to deal with. When they begin to grow air must be gradually given till the plants are inured to the atmosphere of the house, when they can be shifted on as required.

OLEA FRAGRANS.—This Olive, remarkable for the delicious fragrance of its blossoms, will strike fairly well from cuttings, but to get up a stock quickly, by far the better plan is to graft them on young vigorous stocks of the common Privet, with which they readily unite and form a lasting union. The stocks are best if established in small pots for the purpose, but if they are not at hand, young, clean plants can be carefully lifted from the open ground and potted. Side grafting is the method usually followed, but it matters little as long as the two portions fit well together. If possible a twig or two should be left on the plant above the graft to maintain a constant circulation of sap till a union takes place. After grafting the plants must be kept in a close frame, either with or without a little heat, till the scions commence to grow, when they should be at once hardened off. The hardy *Osmanthus* can also be propagated under exactly the same conditions, and using the same stocks as for the *Olea*. At the same time they will strike from cuttings, but, as in the case of the other, grafted plants make the quicker progress during their earlier stages. Standards of the *Osmanthus* may be formed by grafting them on tall, stout stems of the Privet. As they require to be kept close till a union is complete, the stocks, if too tall to stand upright in the frame, can be laid down, as this does not affect the progress of the union in any way, provided they are stood up and watered when necessary.

ANTHURIUMS.—The seeds of these take a long time to ripen, as those originating from the blooms that were fertilised last year are only now fit to gather. The small round fruits containing the seeds should be allowed to remain on till they turn red and are ready to drop, when they may be gathered and rubbed up with a little dry sand, in order to remove some of the glutinous substance in which the seeds are embedded. If laid on a shelf for a

little while they get dry enough to allow the sand to be separated from the seed, which will then be ready for sowing. The pots prepared for the reception of the seed must be well drained, and then filled to within half an inch of the top with a compost consisting of peat, chopped Sphagnum, and silver sand. After the seeds are sown they may be covered with pure silver sand and placed in a close propagating case, for a humid atmosphere is very necessary to their well doing. After germination takes place and the young plants are large enough to pot off, they should be put into small pots, using the same kind of soil, and after that returned to their same quarters, as they make much more rapid progress if kept close during their earlier stages. As division is so readily effected in the case of *A. Scherzerianum* and its varieties, seedlings are seldom raised; yet if needed they can be without difficulty, and young plants produced in this way will yield plenty of interest as the flowers expand. In the case of plants that are divided, they do much better if kept close for two or three weeks after that operation. T.

TREES AND SHRUBS.

W. GOLDRING.

THE WEYMOUTH PINE.

(*PINUS STROBUS*.)

THE history of cultivated trees in England commenced with the introduction of many of the finest forest trees of North America, and among these is the Weymouth Pine, or white Pine, as it is called by the American lumbermen. It has been in this country for upwards of 180 years, and as it has been extensively planted, it is a familiar tree in all parts of the country. It is quite as much at home as the Scotch Fir, Larch, or Spruce, and, like them, has become naturalised. But it has not been planted so largely as a timber tree as the Scotch Fir or Larch, as its timber is comparatively worthless, a singular fact, seeing that in America it is one of the staple woods of the country, and is, in

An old Weymouth Pine (*Pinus Strobus*).

fact, used more than any other Pine in the States, for, according to Michaux, the majority of the houses in the earlier towns of the Northern States were constructed of white Pine, so that it is remarkable that with us the timber is so inferior. But we have here to look upon it more as an ornamental tree, or at least its uses apart from its timber.

In the neighbourhood of old estates the Weymouth Pine is a familiar tree, as it used to be largely planted during the last century, for throughout the country its merits as a timber

tree for shelter and for ornament were extolled, and in some estates, especially at Longleat, in Wiltshire, large plantations were formed of this tree alone; indeed, Lord Weymouth, who then owned Longleat, planted such large quantities of it that it has ever since been commonly known as the Weymouth Pine. It is a tree possessing considerable beauty both in its juvenile and adult stages. A young tree well developed and vigorous is admirable, its light feathery foliage being of that pale glaucous green tint which is only seen in the group of Pines to which *P. Strobus* belongs, and which includes *P. monticola*, *Lambertiana*, and *excelsa*. In fact, it is these that have in a great measure supplanted the Weymouth Pine in ornamental planting, as they are all newer introductions, though scarcely more beautiful and certainly not so hardy.

This Pine is not a tree for all soils and situations, as a number of other Pines are. It dislikes a bleak exposure, and a seaside exposure is fatal to it. It must have shelter to do well, such as that afforded by hills or plantations. Its favourite soil is a gravelly loam, though it grows freely on sandy gravel. Clay it

it grows to a height of 150 feet, with trunks as straight as ship masts.

The Weymouth Pine belongs to the *Strobus* section of the genus, all of which have five leaves in a sheath. The leaves are much shorter than those of its Himalayan congener, *P. excelsa*, but longer than those of *P. monticola*, which is another American Pine. The leaves and cone are well shown in the accompanying engravings, so that a description of them is scarcely necessary. It may be always recognised at a distance by its ashen-grey, smooth bark and its thin, feathery foliage. There are a few very distinct varieties of it, the most important being the dwarf form called *nana*, which is quite a pigmy, of globular outline, and very dense.

Robus deliciosus.—From the great beauty of this Rocky Mountain species of Bramble one would expect to find it in general cultivation. Such, however, is not the case, as not only is it a rare shrub in gardens, but it is by no means common in nurseries. This is not owing to the plant having been so recently introduced that a sufficient time has not elapsed to work up a stock, for it has been known for years, and though frequently noted in

The Weymouth Pine (*Pinus Strobus*); branch and cone (reduced size).

objects to, or, in fact, any kind of waterlogged soil. The heaviness or lightness of the soil is easily discernible where this Pine is planted. On heavy soils the growth is dense, while on light soils the foliage is comparatively scanty, and the branches and trunk more spindly. The accompanying illustration shows fairly well the appearance of the adult stage of the Weymouth Pine, the large tree being a portrait of one that grew in Studley Park, being at the time over 60 feet high. Large specimens of the Weymouth Pine are not uncommon, and probably the finest in Europe are those at Longleat, which were among the first planted in this country. There are several groups of magnificent trees still in the greatest vigour, some being nearly 100 feet high, and girthing as much as 8 feet in circumference. This, however, is not an extraordinary size considering that the trees were planted over a century ago. This Pine is, in fact, not a fast grower compared with most other Pines, its average rate of growth in this country not being much more than 1 foot a year.

In its native woods, which extend from Canada through the Eastern United States to Virginia,

THE GARDEN, its merits, generally speaking, seem to be ignored. This species of *Robus* is widely different from our common Brambles, for it forms a much-branched bush with lobed leaves, and is altogether devoid of spines; indeed, in general characters when out of flower it bears a certain resemblance to a Currant. The blooms are large, pure white in colour, and borne in such profusion that a specimen when seen at its best is one mass of white. With regard to its propagation, I have succeeded fairly well with this Bramble by taking cuttings of the growing shoots about midsummer and putting them under a hand-glass in sandy soil. Root cuttings, too, will often yield a few plants, and when once started they grow away quickly.—T.

Daphne Genkwa.—This differs very much from the other *Daphnes* in general appearance, and is at the same time of especial interest from its early flowering habit, blooming as it does in March or April before the expansion of the foliage. It forms rather a neat growing deciduous shrub, with deep green, lanceolate leaves and small clusters of flowers, which are disposed thickly along the still leafless branches. The individual blooms greatly resemble both in colour and shape those of a Lilac (*Syringa*) the tube being about half an inch long. It is fairly hardy around London, but, owing to its early blooming qualities, is seen at its best when treated as a

wall plant. It is a native of Japan, and was introduced by Fortune, but was apparently lost again till re-introduced into this country about twenty years ago through the Botanic Gardens, St. Petersburg, but its merits do not appear to have been recognised till within the last two or three years. A couple of years ago it was shown in such good condition at one of the spring meetings of the Royal Horticultural Society as to be awarded a first-class certificate.—T.

SOCIETIES AND EXHIBITIONS.

ROYAL HORTICULTURAL.

APRIL 26.

THE meeting of the fruit and floral committees was held in the conservatory, and was rendered very attractive by the fine groups of Roses in pots, collections of Orchids and hardy flowers, and also by the fine display made by the southern section of the National Auricula Society, who also held their show on this occasion.

First-class certificates were awarded to the following, viz. :—

Primula obtusifolia Gammiciana, exhibited by Mr. J. Douglas, Great Gearies, Ilford.

Narcissus Johnstoni, from Messrs. Barr and Sons, King Street, Covent Garden.

Trillium sessile californicum, from the New Plant and Bulb Company, Colchester.

Primrose Mrs. Wilson, exhibited by Mr. G. F. Wilson, Weybridge.

Odontoglossum vexillarium leucoglossum, from Mr. Tautz, Hammersmith.

Odontoglossum Cambridgeanum, sent by Mr. R. J. Measures, Cambridge Lodge, Camberwell.

Amaryllis Ambient, from Messrs. Veitch and Sons, King's Road, Chelsea.

A fine group of dwarf-trained Roses in pots was exhibited by Messrs. Lane and Sons, Berkhamstead. These were excellent, the most notable being Étienne Levet, Royal Standard, Fisher Holmes, John Keynes, Mme. Victor Verdier, Richard Wallace, La Rosière, Ed. Morren, and Hippolyte Jamain. A silver-gilt Banksian medal was awarded.

Groups of Roses, consisting of standards and dwarfs, also cut blooms, were sent by Mr. Rumsey, Joyning's Nursery, Waltham Cross; and also by Messrs. Paul and Sons, Cheshunt, each of whom received a silver-gilt Banksian medal.

Cut Roses were staged by Mr. Walker, Thame, Oxford, amongst which a box of *Maréchal Niel* were conspicuous for size and colour. A similar box of *Niphotos* were remarkable for their size and purity. A silver Banksian medal was awarded.

Rhododendrons were shown by Messrs. Lane and Sons, and the group deservedly received a silver Banksian medal.

Among the Orchids shown upon this occasion were *Oncidium macranthum lamelligerum*, from Mr. R. J. Measures, of Camberwell. This is said to be a natural hybrid between *O. macranthum* and *O. serratum*. The flowers are of a bronzy hue, the upper portions of the petals being yellow. From the same exhibitor came a beautiful group of *Trichopilia*, amongst which were *T. lepida rosea*, *suavis*, and *suavis alba*, also a very fine hybrid *Odontoglossum* called *Cambridgeanum*. It had somewhat the appearance of a cross between *O. Halli* and *crispum*; the flowers are large, sepals and petals rich deep chocolate, lip large and flat, cordate, apiculate, white with a large blotch of reddish crimson at the base, the crest deeply fringed.

The same exhibitor also sent cut blooms of the rare and beautiful *Cypripedium Wallisi*, a species belonging to the caudatum group, introduced from Ecuador; the sepals are light canary yellow, petals very long, slightly duller in colour, pouch large, fawn colour on the outside, profusely spotted within with dull crimson; mouth of the pouch milk-white with a continuous border of crimson.

Mr. Smee, of The Grange, Wallington, sent *Phala-*

nopsis Sanderiana alba, which much resembled *P. amabilis* in general appearance.

Messrs. Shuttleworth and Garder, Clapham Park Nurseries, sent a fine specimen of the rare and little-known *Cymbidium tigrinum*, bearing fifteen handsome flowers.

Mr. Bond, Elstead House Gardens, Godalming, staged a group of *Cattleya Mossia* in bloom, also cut flowers of *C. Mendeli* and a hybrid *Odontoglossum crispum*, the ground colour yellow, blotched with chocolate.

Mr. Tautz, Studley House, Hammersmith, sent a pretty group comprising *Odontoglossum radiatum*, a fine spotted form of *O. crispum*, *Dendrobium Wardianum candidissimum*, *Cattleya Lawrenceana*, *Odontoglossum vexillarium leucoglossum*, &c. The New Plant and Bulb Company, Colchester, contributed a plant of *Cattleya Trianae Schroederae*.

Amaryllids were staged by Messrs. Veitch and Sons, of Chelsea, and Messrs. Paul and Sons, the Old Nurseries, Cheshunt. In Messrs. Veitch's collection we noted *Credo*, a deep crimson flower, shaded violet, white star; *Ambient*, vivid crimson-scarlet, good shape and substance; *Czarina*, white, beautifully flaked and tinged with magenta-rose; *Endymion*, deep crimson, shaded purplish violet, flaked with white.

Groups of *Narcissi* were contributed by Messrs. Barr and Sons, King Street, Covent Garden, Messrs. Collins and Gabriel, Waterloo Road, and by Mr. Ware, of Tottenham. These were all very handsome groups, less crowded than is usually the case, and being arranged with their own leaves were very pleasing. A silver Banksian medal was awarded to each. Another handsome group was shown by Mr. James Walker, Whitten, Middlesex, for which also a silver Banksian medal was awarded.

Alpines were exhibited by Messrs. Paul and Sons, the Old Nurseries, Cheshunt. This was a remarkably fine group, amongst which we noted *Soldanella minima*, *Anemone Robinsoniana*, *Pulmonaria dahurica*, *Sanguinaria canadensis*, *Ranunculus crenatus*, *Aubrietia tauricola*, *Draba brunkifolia*, *Saxifragas arctioides alba* and *præcox*, *Houstonia cærulea alba* and *serpyllifolia*, *Dentaria polyphylla*, *Alyssum podolicum*, *Erythronium americanum*, *Androsace Chamæjasme*, *Primulas*, *Doronicums*, *Narcissi*, *Violas*, *Calthas*, *Muscari*, and other hardy gems. These were awarded a silver Banksian medal. A group of alpines also came from Mr. T. Ware, Hale Farm Nurseries, Tottenham, to which a similar award was given.

A group of *Primulas* also came from the Royal Gardens, Kew, containing many beautiful and interesting species, amongst which the following were conspicuous: *P. rosea*, *verticillata*, *Balbisii*, *specabilis*, *japonica*, *obconica*, *denticulata*, *hirsuta*, *intermedia*, *ciliata*, *Balfourii*, *Palinuri*, *viscosa*, *biflora*, &c. A silver Banksian medal was awarded. Primroses were sent by Mr. A. Waterer, Knap Hill Nurseries, Woking, and were awarded a bronze Banksian medal. They consisted of a rich and varied collection of coloured forms of the common *Primrose*.

Mr. R. Dean sent *Viola Miss Barron*, a tufted Pansy with creamy white flowers, with a few streaks of purple round the small yellow eye.

Mr. Owen, nurseryman, Hartford, Cheshire, staged *Polyanthus Queen Victoria*, a double-flowered kind, crimson with gold keeing.

Mr. Millar, Southdown Nursery, Shoreham, sent a large tray of a variety of *Myosotis dissitiflora*, which appeared very compact in growth, whilst the flowers were large and conspicuous.

Mr. Wilson, Heatherbank, Weybridge, sent *Primula Mrs. Wilson*, a variety with rich purplish violet flowers having a yellow eye; and a little miniature species named *P. Pylabra*, which resembled a very minute plant of *P. denticulata*.

From the New Plant and Bulb Company came *Trillium sessile californicum*, a plant with marbled foliage, bearing large handsome white flowers, stained at the base with crimson.

Primula Kingi, sent by Messrs. Veitch and Sons, Chelsea, is a variety with pendulous yellow flowers, the calyx being slightly farinose. A plant very

similar, if not identical, was exhibited by Mr. J. Douglas under the name of *P. reticulata*. It is said to grow naturally in wet rocky places in Northern India, at some 11,000 feet elevation. Mr. Douglas also staged the beautiful *P. obtusifolia Gammiciana*.

Messrs. Standish and Co., nurserymen, Ascot, staged a large and handsome group of *Erica Wilmoreana*. The plants were well grown and profusely bloomed, amply illustrating the value of this kind for early spring use.

Mr. Bannister, Westbury-on-Trym, exhibited a new white-flowered Mignonette, named *White Perfection*, apparently robust in habit, with very large white fragrant blooms.

Mr. Chambers, of Isleworth, again sent his very fragrant dark blue double-flowered *Violet Queen Victoria*.

Fruit committee. Apples were sent by Messrs. Cheal and Sons, Lowfield Nursery, Crawley, Sussex. The collection comprised sixty dishes, amongst which we noted the following as being in excellent condition: London Pippin, Beauty of Kent, Lane's Prince Albert, Golden Reinette, Winter Peach, Galloway, Lord Derby, Wellington, King of the Pippins, Gloria Mundi, Hereford Pearmain, Reinette du Canada, Blenheim Orange, Tower of Glamis, Ribston Pippin, Golden Mundi, Cox's Orange Pippin, and Emperor Alexander. They were awarded a silver Banksian medal for the collection. Mr. A. Smee, The Grange, Wallington, Surrey, sent fifty dishes of Apples, all sound and bright, the most notable being Henry Moming, Wallington Beauty, Duck's-bill, Winter Coleman, Omar Pasha, Lane's Prince Albert, Cox's Pomona, Dumelow's Seedling, Orange Goff, Beauty of Kent, Blenheim Orange, Winter Pearmain, Fall Pippin, Lady Hayes, Cellini Pippin, Cove Pippin, and London Pippin. A silver Banksian medal was awarded. Mr. Mundell, Moor Park Gardens, Rickmansworth, staged a collection of twenty-eight dishes; and Mr. Divers, Wierton House Gardens, also contributed a collection of twelve dishes; these were also in excellent condition, and for the most part consisted of the kinds enumerated above.

NATIONAL AURICULA AND PRIMULA SOCIETY (SOUTHERN SECTION).

THE annual exhibition of this society took place in connection with the meeting of the Royal Horticultural Society on Tuesday last. The Auricula being a flower that is grown only by a few for exhibition purposes, the number of exhibitors is necessarily limited, and it seemed as if they were fewer than usual on this occasion; had not several growers come up from the north, the exhibition of southern-grown flowers would have been a comparatively poor one. The Rev. Mr. Horner brought from his northern home, as usual, flowers of excellent character, but, as a rule, they appeared somewhat rough and lacked that smoothness and symmetry which constitute high quality in this flower. Perhaps some of the plants are grown too strongly to be consistent with quality in the flowers; at the same time, if trusses of eight to ten pips are to be had, high culture is necessary to produce this. The season proved a very trying one, being cold, changeable, and retarding, and advantage had to be taken of artificial warmth to get the trusses developed in time for the show. The growers did their best, but they had a stiff battle with adverse influences.

SHOW AURICULAS. In the class for twelve varieties of show Auriculas, the Rev. F. D. Horner, Lowfield, Kirkby Lonsdale, was an easy first, having in the main flowers of his own raising. Of green-edged varieties he had *Ivy Green*, *Merlin*, and the Rev. F. D. Horner; of grey-edged flowers, *George Lightbody*, *Fairy Ring*—a fine and promising flower—and *Candida*; white-edged, *Magpie* and *John Simonite*; selfs, *Heroine*, *Dulcic*, *Rubra*, and Mr. Douglas. Mr. J. Douglas, Great Gearies, Ilford, came second, but a certain amount of roughness and over-development appeared to characterise several of his varieties. He had, of green-edged flowers, *Abbé Lizet* and *Prince of Greens*; grey-edged, *George Lightbody*, *Mabel*, *Sylvia*, and Mr. Moore; white-edged, *Marmion*, *Dr. Kidd*, and *John Simonite*;

sels, Negro, Sir William Howett, and a shaded purple flower unnamed; third, Mr. W. Bolton, Warrington. Two other prizes were awarded. Mr. Horner also had the best six plants, staging of green-edged the Rev. F. D. Horner; grey-edged, Grayling and George Lightbody; white-edged, Miranda; sels, Heroine and Kathleen; second, Mr. H. W. White, Killingworth, Newcastle-on-Tyne, who had of green edges, Prince of Greens (perhaps as fine as ever it was shown) and the Rev. F. D. Horner; grey-edged, Luna and George Lightbody; white-edged, Beauty; self, Mrs. Douglas; third, Mr. F. Pohlmann, Halifax. Mr. A. Potts, Hoole Hall, Chester, had the best four plants, staging good examples of the Rev. F. D. Horner (green), George Lightbody (grey), Mrs. Dodwell (white), and Mrs. Douglas (self); second, Mr. S. Barlow, Stakehill, Manchester, with Miller's Green (green), George Lightbody (grey), Acme (white), and Carbuncle (self); third, Mr. W. L. Walker, Barley, Reading. Mr. A. Potts also had the best two specimens in the Rev. F. D. Horner and John Simonite; Mr. Barlow being second with George Lightbody and Black Knight; third, Mr. A. Spurling, The Nest, Blackheath.

Single plants of Auriculas were scarcely so numerous as usual. The best green-edged flowers given in the order of merit were Prince of Greens, Rev. F. D. Horner, Lancashire Hero and New Green. The best grey-edged were Florence (Douglas), Richard Hoadly, George Lightbody, and Silvia. The best white-edged—Acme, Beauty, Luna (Horner), John Simonite, and Conservative. The best sels—Sir William Hewitt, Heroine, Pizarro, Mrs. Douglas, Ellen Lancaster, Lord of Lorne, and Loveliness (Barlow).

In the class for fifty plants, one which is imposing from the number staged, but in which the inferior rather than the best flowers find a place, Mr. J. Douglas was first, and his group contained the following: Green-edged—Abbé Lizst, Verdure, Campbell's Green, and Prince of Greens. Grey-edged—Marmion, Frank Simonite, John Waterson, Mabel, Richard Hoadly, Jumbo, Dr. Horner, Ajax, and Alexander Meiklejohn. White-edged—Acme, Smiling Beauty, Beauty, Sophie Dumaresque, Conservative, and Dr. Kidd. Sels—Teresia, Pizarro, Dignity, Vulean, and Sir Lancelot. Second, Mr. C. Turner, with green-edged—Mrs. Batcher, Mrs. Knighton, Duke of Wellington, and General Havelock. Grey-edged—Colonel Champeys, C. E. Brown, Dr. Horner, Robert Trail, Competitor and Frank Simonite. White-edged—Beauty, Acme and John Waterson. Sels—Vulean, Bacchus, C. J. Perry, Meteor Flag, Lord of Lorne and Clipper.

The trustees of the Turner memorial offered prizes for six show Auriculas, open only to amateurs, and here Mr. W. Bolton was first with Prince of Greens, Rev. F. D. Horner, Lancashire Hero, Reliance, John Simonite, and Mrs. Douglas; second, Mr. T. E. Henwood, Reading, with Lancashire Hero, Rev. F. D. Horner, George Lightbody, Conservative, Black Bess and Pizarro; third, Mr. C. Phillips.

Prizes were also offered for seedling Auriculas, and in the class for green-edged flowers Mr. Bolton was first with James Douglas, and the Rev. F. D. Horner second with Conquest. Grey-edged—first, Mr. Bolton, with Samuel Barlow; second, Mr. S. Barlow, with Grey Friar. White-edged—first, the Rev. F. D. Horner, with Amanda. Sels—first, Mr. J. Douglas, with Perfection; second, the Rev. F. D. Horner, with Red Rover.

The premier show Auricula, selected from the whole show, was a very fine Prince of Greens, shown by Mr. H. W. White, in his second prize lot of six plants.

ALPINE AURICULAS.—These were somewhat numerous shown, but they lacked the finish and brightness usually seen in this class. Mr. C. Turner had the best twelve, staging Mrs. Llewellyn, Eclipse, Wrestler, Sceptre, Mungo, McGeorge, Garnet, Faust, Sunrise, Sir H. Darvill, Symmetry, Lady H. Grosvenor, and Edith. Second, Mr. James Douglas, with Unique, Love Bird, King of the Belgians, Princess of Waldeck, Rosamund Fellowes, Elvina, Lady H. de Walden, Queen Victoria and seedlings. Mr. C. Turner also had the best six, staging Mungo,

McGeorge, Unique, Sunrise, Symmetry, Acquisition, and Olympia. Second, Mr. J. Douglas, with Diadem, Unique, Love Bird, Princess of Waldeck, Ada, and Lady H. de Walden. Third, Mr. A. Spurling. The best four came from Mr. S. Barlow, who had three of his own raising, viz., Velvet Fife, Polly and Charley, and Mrs. Meiklejohn. Second, Mr. F. Pohlmann, with four pretty faced varieties. Third, Mr. T. E. Henwood. Then followed prizes for the best single specimens, gold centres: first, Mr. C. Turner, with Sunrise, and second, Lady H. Grosvenor; third, Mr. Pohlmann, with Emir; fourth, Mr. Douglas, with Love Bird. White centres: First, Mr. C. Turner, with Lady H. Crowe; second and third, Mr. J. Douglas, with Ada and Queen Victoria; fourth, Mr. C. Turner, with Florence. The best seedling golden centred flower was Charles Needham, from Mr. S. Barlow; Mr. C. Turner coming second with Sunrise. The best white-centred flower was Lady H. Crowe, from Mr. C. Turner; Mr. Douglas being second with Ada.

POLYANTHUSES, GOLD-LACED.—Some choice varieties in excellent character were shown by Mr. S. Barlow, of Manchester, who was first with six plants, having George the Fourth, Exile, Cheshire Favourite, Prince Regent, Lancer, and Sunrise. Second, Mr. J. Douglas, with Exile, Formosa, Prince Regent, William the Fourth, Lancer, and George the Fourth. Mr. Barlow also had the best three plants, viz., Sunrise, Prince Regent, and Exile; second, Mr. W. Bolton, with Exile, Cheshire Favourite, and Prince Regent. The best specimen was Naxara, from Mr. J. Douglas; second, Mr. Barlow, with Exile, and third, with Cheshire Favourite.

FANCY POLYANTHUSES.—These, though well shown by Mr. B. Dean, Ealing, who was placed first with twelve fine plants, were, owing to the lateness of the season, not up to the usual mark; Mr. Douglas was a good second.

SINGLE PRIMROSES.—These were very bright. Mr. R. Dean being first with a fine bright lot; Mr. J. Douglas being second, and Messrs. Paul and Son third.

DOUBLE PRIMROSES.—Messrs. Paul and Son were the only exhibitors of these, having large and striking pans of Crossii, platypetala plena, Harlequin, purple, sulphur, and white; second, Mr. H. S. Leonard, St. Catherine's, Guildford, with white, old velvet crimson, platypetala plena, purple, crimson-purple, and Crossii.

SPECIES OF PRIMULAS.—The best collection of twelve came from Mr. J. Douglas, who had a good representative lot, consisting of *P. Sieboldi* lilacina, obconica verticillata, rosea, denticulata, nivea, pubescens, villosa, marginata, ciliata, intermedia, and ciliata coccinea; second, Messrs. Paul and Son, with *P. sinensis*, ciliata purpurea, nivea, auriculata, denticulata, &c. Mr. S. Barlow had the best six, setting up *P. obconica*, denticulata, intermedia, rosea, viscosa, and nivea.

First-class certificates of merit were awarded to the following show Auriculas, all of a very fine and promising character: Amanda (Horner), Samuel Barlow (Bolton), James Douglas (Bolton), Sir William Hewitt (Douglas), Magpie (Horner), Dulcie (Horner), Grayling (Horner), Edward Pohlmann (Turner), Rubra (Horner), and Abbé Lizst (Douglas).

NARCISSUS COMMITTEE.

A MEETING of the committee was held at South Kensington on Tuesday, April 26, when a number of specimens were submitted. The chief interest lay in the following:

Mr. Maw showed the flowering scape (dried) of *N. tazetta* papyraceus, which he had found south of Tangiers, and which was considerably over 2 feet in length; also a collection of the different typical forms of British pseudo-Narcissus for comparison.

Mr. Wolley Dod sent Portuguese forms, supposed hybrids between triandrus and pseudo-Narcissus, bearing a remarkable resemblance to Johnstoni.

Mr. Kendall brought a very fine seedling from Emperor, similar in form, but of a citron colour; a bold flower, of good substance. It was resolved to register it as The Czar. Other good seedlings the

committee desired to see again; and a pseudo-Narcissus (? hybrid) of very perfect form, always quite constant, was registered as Vicar of Lulworth.

Mr. Corder sent flowers of Portuguese varieties collected last year; and Mr. Threlfall showed dried flowers of a *Tazetta* he had received from the Canary Islands. Flowers of Johnstoni were received from several sources.

A number of the older and better-known varieties were considered, and it was resolved to register the following: Emperor, J. B. M. Camm, Horsfield, Empress, Sir Watkin, C. J. Backhouse, Princess Mary, Minnie Hume, Beatrice, Mary Anderson (Leeds), Gem (Barri), conspicuous.

Attention was drawn in a communication from Mr. Wolley Dod to a disease to which Daffodils are subject, and which was very prevalent in his garden this year. The Daffodil comes up weakly at the end of winter, the green leaves soon become brown at the points, and their growth is arrested. When dug up the bulb is found soft and rootless. It generally attacks whole clumps, by which it would seem to be contagious; the germs are in the bulbs the previous summer, for clumps that have been divided in July and replanted in different soils have all shown the disease in the following spring. It did not appear to be attributable to frost nor to imperfect maturing, for in the wetter and more sunless parts of the garden, where the leaves of Daffodils remain green almost till it is time for them to start again, no signs were seen of it.

Many members of the committee stated that they had found this disease especially prevalent this year; all classes of Daffodils seem to have been attacked alike, and not only those of more delicate constitution. Mr. Wilks had suffered chiefly in the wetter parts of his garden, but he thought it had arisen from too heavy or too fresh a dressing of manure. Observation is specially requested to this disease, and the committee will be glad to receive intimation of any facts bearing on the question of its origin. C. R. SCRASE-DICKINS, *Hon. Sec.*

The Matrix Draught and Dust Excluder.

Will you allow me to draw your attention to the accompanying matter, which I venture to think, you will consider of public interest, seeing the admitted difficulty all householders experience in finding a reliable means of freeing themselves from troublesome and dangerous draughts from doors, windows, and other crevices. The Matrix Excluder is on an entirely fresh principle, and I am encouraged to place it before the public, because I consider that the excluder fulfils perfectly all the requirements for the purpose, and is the first thing introduced which has done so. If you will try the sample on any door or window I believe you will be pleased with it. T. J. PORTER.

** We have received from Mr. T. J. Porter, of Fleetwood, a sample of his Matrix Draught and Dust Excluder, and have submitted it to our architect, Mr. William Simmons, of 92, Long Acre, who reports it admirably adapted for the purpose intended, but adds that in an intelligently warmed and ventilated house there can be no objectionable draughts, however ill-fitting the joinery may be.—Ed.

WOODS & FORESTS.

"YORKSHIREMAN."

MISMANAGED TREES.

As "B. T." (p. 386) speaks of "extensive tracts of land throughout the country," and goes on to speak of "all such cases as those in question," I apprehend him to advocate the "trenching 2 feet deep" of the said extensive tracts if the preparation of the land is to "be of a nature to give a reasonable chance for the well-doing of the trees after they have been planted." If this interpretation is correct, I dispute it *in toto*, and I would only recommend "B. T." to go to the nearest wood planted on the natural soil without any trenching to see how far wrong he is. I do not dispute that a young plantation will make perhaps the best start in newly trenched ground, but the cost is out of all proportion to the return that may be expected even by the most sanguine, and the advantage is only temporary, as the tree gets hold of the subsoil very soon below the trenching line. Moreover, what is added to any soil by trenching at 2 feet deep, manure being out of the question? Answer, nothing. The hard crust is broken up a little deeper; that is all; nothing is added. I could show thousands of marvellous examples, all tending to show the uselessness of trenching, and on very dry bottoms, too. "B. T." himself quotes examples proving that "deep down where the principal feeding roots exist" the roots are quite beyond the advantage of the 2-feet trenching, and then, forgetting this, goes on soon after to tell us that the said trenching is indispensable. It is this kind of ill-digested writing that misleads people. Do not trench for timber trees if you expect any return for your labour and planting. In past times, and lately here, tracts have been planted successfully where the soil was apparently so thin and rocky, that it cost as much to make the pits for planting as would in some places cost for buying, pitting, planting and all together. Yet the trees have done well and will produce good timber in time, as they have done before in the same places.

"B. T." says that the want of thinning makes the trees grow like a plantation of "clothes props." There could not be a better sign of good management. The trees must have top room, of course, to produce the thickness of trunk required, but the nearer they approach the shape of clothes props the better for those who have to sell them, as such trees are worth from ten to twenty per cent. more than any other.

"B. T.'s" alleged robbing the soil of its moisture by having too many trees upon it does not amount to much, as I am pretty sure no plantations are killed or much injured in this country for want of moisture at the root. It does no good to invent possible causes of mischief; let us see them. Besides, if thick planting robs the soil of the moisture, how is it going to be helped if the trees left are sufficient to take up the ground that is cleared and absorb the same quantity of moisture as the thicker plantations of smaller trees would have done?

Rings in trees and in the trade.—I trust "Yorkshireman" and other experienced foresters will continue to favour your readers with their experience on both subjects. Possibly the rings in the trade are the more difficult to deal with. That they exist no one of wide experience can doubt. They are not only felt at sales, but in some private contracts. The timber trade in many localities is so limited as almost to be a close corporation. Frequently one man dominates a county or district,

and it is seldom that the influential factors of it exceed half-a-dozen. Tacit understandings about prices are therefore easily arrived at and as easily enforced. No one can urge very valid reasons against tacit understandings, but the modes of controlling prices are sometimes most objectionable. They are also said to be unlawful, but I have never met with any statute that expressly forbids one or more purchasing for the many at auctions, and arrangements being made afterwards for a virtual re-sale among the members of the ring at prices, thus beaten down by an unfair monopoly in buying. Similar tactics are at times adopted in sales by private contract. The writer had some valuable timber to offer this winter. An offer was made by a large merchant, being preposterously under value. For several days the same offer, with the slightest possible variation, was made from several quarters. At first blush this appeared almost conclusive of the reasonableness of the first offer. Unfortunately, however, from this view of the matter, abundant evidence was forthcoming that the several offers were merely rebounds of the first. An underground railway of woodmen, haulers, &c., seems to exist in some neighbourhoods, whose interest, it seems, is to depreciate the value of timber. Sellers for these and other reasons can hardly be too reticent and prudent about prices, values, &c. Of course there are timber merchants far above these questionable tricks of the trade, and when the seller meets with such he should sell to them at reasonable prices and stick to them. But unfortunately, members of the rings will occasionally far out-bid these at times, and for special and what seems inscrutable purposes, I have even seen honest buyers driven off the field by mere speculative bidding for a time, until the speculators had it all their own way towards the close of the sale. Shrewd auctioneers, who know their men, can do much to check the evils of rings. But on the whole, timber is most profitably sold to honest merchant-by private contract, a mode of selling that if generally adopted would speedily break up the rings in the trade, and ensure fair profits alike for seller and purchaser. Reports that have reached me from the "Golden Crown" as to the second sales of some timber rings reflect most severely on some portions of the trade, and ought to be rendered impossible in the future. CALEDONICUS.

THE CLUSTER PINE.

(PINUS PINASTER.)

THE rugged grandeur of a well-grown specimen of the above Pine was never more forcibly brought home to me than a few days ago when paying a short visit to the old Roman villa at Caerhun—a charming spot pleasantly situated on a rocky eminence in the vale of the Conway. Often enough do we hear the Cluster Pine spoken of as an excellent tree for planting in exposed seaside situations, even in poor, drifting sands, and a capital subject it is for such places, but far more rarely, indeed, is it mentioned as a fitting Pine for the ornamentation of our parks and lawns. That it is, however, admirably adapted for such places is beyond doubt, its tall, massive, and rugged stem, its far-spreading, flatly-rounded head, and refreshing light green foliage, which contrasts so markedly with the numerous clusters of terra-cotta coloured cones, all combining to impart an air of massive grandeur that is, I think, hardly surpassed by any member of the family to which it belongs.

But, apart altogether from its ornamental qualities, this Pine is peculiarly adapted for planting in even the most exposed parts of our wind-swept isle, a statement the truth of which can be well borne out by the numerous fine trees which exist all along the coast from the most northerly point of Scotland, where it hardly raises its head 12 feet in height, to the more genial surroundings of Southern England, where specimens 70 feet high are not at all uncommon.

It has been used with the most satisfactory results for the double purpose of binding the shifting sands on the sea-coast and reclaiming vast tracts of maritime lands from sterility, uses for which it is peculiarly well adapted, as it will grow and attain to a large size, down even to high water mark, and where exposed to the most keen and

searching winds, and where the roots have nothing to wander amongst save vast banks of sand. On the sandy shores of the Bay of Biscay, the Landes of France, as well as in Scotland and England, the Cluster Pine has been turned to good account, and now covers vast tracts of ground that previous to planting were but dreary and monotonous stretches of worthless, shifting sands. No other tree is so well adapted for binding these sands and rendering them fertile as the one in question, and no other tree affords such an amount of shelter or is so peculiarly fitted for withstanding the almost constant hard-blowing gales of our coast lines.

Strange to say, the Pinaster is not a satisfactory tree for planting far inland; indeed, in order to ensure satisfactory growth it requires a hot climate and deep sand, no matter how barren this latter, so as to allow of the free penetration of its long tap root, which, more than of any other Pine, is a marked characteristic of the one in question. The lateral roots are not at all abundant and of weak growth, even they having the inclination to emit miniature tap roots rather than the fibrous-spreading ones that tree planters place so much dependence on for safety and ease in removal. We have tried for years to get home-raised seedlings of the Pinaster to produce bushy, fibrous roots, but all to no purpose, annual transplanting and the best of management otherwise being found of little avail in furthering such an object. Staking, and that of the firmest description, must be resorted to when a specimen of the Pinaster is placed *in situ*, and not only must this be performed when the young tree is planted out, but in our own case we have had to pay strict attention to the same for upwards of a dozen years afterwards. On the lawn at Penrhyn Castle, where the south-western wind blows almost unchecked, a number of these trees, in conjunction with *P. Laricio*, were planted thirteen years ago, and the amount of trouble the Pinaster has given to keep it on its feet is simply surprising, and contrasts strangely with the sure-footed *Laricio* that has received no attention, save, indeed, the commonly used wooden stake placed alongside at time of planting, and to which the stem was tied. In contradistinction to this, the specimens of Pinaster had each three strong wires placed at angles around the stem and firmly fastened to stout stakes driven into the ground at a distance of 6 feet from the same. Sure as we generally consider this method of mooring trees, yet it was not sufficient, the dense, heavy head and few roots acting as powerful motors in rendering such a practice of staking or staying as not to be fully relied upon. To-day I have been examining the roots of a number of these trees in the home nursery here that were raised from seeds saved on the estate, and found that even in the hard soil where they grow the long tap-root and its usually three minor brethren strike down almost perpendicularly to a great depth, those of 2-feet high plants having succeeded in finding their way for fully 18 inches into the hard soil, and those of 1 foot for fully 2 feet in depth. Now, in lifting such specimens for final planting out, it is well-nigh impossible to do so without injuring these long, though stout, roots, and if this is done a considerable time elapses before side roots are emitted to take their place. Even could the plants be successfully lifted with their 6-foot or 9-foot long roots, another difficulty immediately presents itself as to how to place these roots when planting the tree, for it is no easy task, if not indeed an utter impossibility, to give them a natural perpendicular position, and too often they are simply spread out, as are those of other Pines on the surface of the pit bottoms.

These evils are, however, easily overcome, and a practical lesson regarding the best method of establishing this Pine may be learnt from the method which was pursued with such commendable success in planting the sandy coast line of portions of France, Spain, and other of the countries bordering on the Mediterranean. The plan adopted with such an amount of success was simply sowing the seeds where the trees were intended to remain, the rearing and putting out of seedlings having been found to be both troublesome and uncertain. From the fact of the Pinaster being of remarkably rapid

growth during the first few years of its existence, it is thus well adapted for such a course of treatment as that above described.

Two-year-old seedlings are not unfrequently 7 inches in height and very bushy in proportion; while plants of six years' growth are frequently more than a corresponding number of feet in height. A few days ago we transplanted from the seed-beds plants of the Pinaster 8 inches in height and 6 inches in diameter of head that had only been sown two years before.

The whole appearance of a full-sized tree of the Cluster Pine was well delineated in *Woods and Forests* of November 19, 1884. The engraving represents a fine tree indeed, that is growing at Monroith, in Wigtonshire, and this so much resembles the fine specimen in the flower garden at Penrhyn, and the larger still tree referred to in the introductory notes of this paper as growing at Caerhun, that I cannot help referring to it, although both the latter trees are of much larger size than the Scottish specimen.

The Caerhun tree is, in truth, a noble specimen of some 72 feet in height, with a stem girthing 15 feet and 1 inch at 5 feet from the ground, and a spread of branches covering a space of 61 feet in diameter. At about 12 feet from the ground the stem divides into two massive limbs, either of which would form, so far at least as size is concerned, a goodly specimen of itself. This tree, as is usually the case, is destitute of branches for about 50 feet, after which height it spreads out into a wide head that is literally crowded with clusters of cones in all stages of development. These conelusters present a remarkable appearance when viewed from beneath, their pretty brownish colour and vast numbers surprising one most.

This tree is growing in a free loam and is much exposed, no neighbouring clump or even single specimen guarding off the dread southern blasts. No age can be ascribed to this tree, but that it was planted but shortly after its introduction to this country is pretty evident. The gigantic specimens of Yew tree growing in the churchyard hard by, one of which is about 19 feet in girth, was, by some members of our Antiquarian Society who visited the old Roman camp lately, said to have been planted 1300 years ago, but if we divide this number by 5, a more correct idea of the Pinaster's age will be arrived at.

The Penrhyn specimen occupies a rather prominent and partially sheltered situation in the flower garden, and is growing in sandy loam of only second-rate quality. It measures 65 feet in height, girths 12 feet at 1 foot and also at 3 feet from the ground level, and the branches cover a space of fully 12 feet in diameter.

The Monreith Pinaster is 61 feet in height, 9 feet 8 inches in girth at 2 feet from the ground, and 8 feet 10 inches at 4 feet from the ground.

Many other fine specimens of the Pinaster might be brought under notice, notably those growing in several of the southern English counties and in various parts of Ireland, notably the north and east.

The Pinaster has nothing of a refined character about it, its whole contour impressing one with an air of rough and simple grandeur. The stem is large, strong, and covered with rough and deeply-furrowed bark; the limbs and branches are contorted and somewhat spiny; the leaves are long, strong, sharp-pointed, and saw-like on the margins; while the whole outline is easy and pleasing in the extreme. For planting in conjunction with other trees, be they conifers or hard-wooded, the Pinaster must not be slighted; but it should always be allowed ample room for the perfect development of stem and branch, for few members of the Pine family present a more wretched or miserable appearance than does a half-suffocated Pinaster. Give the Cluster Pine plenty of room and it will develop a fine, sturdy trunk, a well-balanced and richly-foliaged head, and be a pleasure to behold; but coddle it up in too close proximity to other trees and you have a weak, half-barkless stem, for the rough bark which is so characteristic of this Pine dies off when dampness caused by overcrowding is

present, branches in all stages of decay, and a few tufts of leaves atop the stem, that remind one far more of the sickly appearance of the so-called golden conifers generally than the bright, healthy foliage of a typical Pinaster.

The branches have usually a semi-upward tendency, and are well covered with pleasant green, slightly serrated leaves, these in full developed specimens being 8 inches or more in length, and arranged in pairs. The cones are in clusters of from half a dozen upwards; a specimen now before me has 37 cones, each 6 inches in length, by about 2½ inches diameter at the widest part, and of a light shining brown when fully matured. In early spring the buds are very conspicuous, this being caused by their great length, white, woolly appearance, and recurved scales.

The timber is of little value, save for very temporary purposes, such as making packing boxes, &c., but it burns readily, and is therefore used extensively for firewood. Although a native of the Mediterranean district, the Cluster Pine is now largely grown in most parts of the world, and I was not a little surprised, though agreeably so, when strolling through the Cape of Good Hope Court in the late Colonial and Indian Exhibition, to see a fine section of this wood, and which I noted down as being "far more resinous and weighty, and of deeper colour than any specimen of the same wood that I had ever seen cut in this country."

Nearly 300 years ago, in 1596, this Pine was introduced to us by Gerard. A specimen, which dated from 1685, was cut down about 1862, it being then dead, at the Bishop of London's Palace at Fulham. This was supposed to be the oldest specimen known, and was, when measured for Loudon in 1835, 80 feet in height.

The following pleasant description by Dr. Fleming of the introduction of the Pinaster to Moffat, in Dumfriesshire, is worth mentioning:—

Dr. Walker, who long occupied with distinction the Chair of Natural History in the University of Edinburgh, was, when minister of the parish of Moffat, regarded as rather of weak intellect in consequence of the fondness which he displayed for weeds and vermin. On returning one afternoon in spring from Edinburgh, he was observed to have the pocket of his coat full of what appeared to be Fir branches. The witnesses now imagined that a crisis in his lunacy had arrived, and began to set a watch on his future motions. He was observed in the course of the evening going forth to a corner of the glebe and putting some plants into the ground. When he had retired to the manse, the spies immediately proceeded to the spot and found that he had been planting some young Firs (that these had appeared as branches sticking out of his pocket), and hence they were led to conclude that their minister was not so great a fool as they had suspected. The plants took root, were protected, and, as trees, now prove an ornament to the glebe, and a monument to the doctor's arboricultural tendencies. These trees must now (1857) be at least seventy-three years of age, and one is 45 feet in height, and 6 feet 3 inches in circumference at the ground; and they to this day preserve the name of Pouch Firs, in memory of the part of the doctor's dress in which they were first observed.

A. D. WEBSTER.

THE CATALPA FOR ECONOMIC PLANTING.

THE Catalpa (*Catalpa bignonioides*), says Professor Sargent, long known and generally planted as an ornamental tree, has of late years begun to attract considerable attention as offering peculiar advantages for economic planting. The wonderful durability of the wood of this tree, long ago pointed out by General Harrison, but until lately imperfectly understood, its rapid growth in good soil, and freedom from attacks of insects, make the Catalpa a most promising subject for general planting in rich, strong soil in any portion of the United States south of the 12nd parallel. Further north it often suffers in severe winters, especially when young; and in the New England States, except in exceptional situations, the soil is not rich enough to make the planting of this tree as profitable as that of many others better suited to reach maturity in that section of the country.

The wood of the Catalpa is soft, light, close-grained, and susceptible of a good polish. In general appearance it closely resembles Chestnut, but, unlike that wood, it is easily "filled," and shows none of the tendency to warp or start which renders Chestnut unfit for the best cabinet work.

Should the wood of the Catalpa ever reach the market in quantity, it will rank with Butternut for cabinet and architectural work, and will make a valuable addition to the hard woods now so freely employed in interior decoration. It is, however, for railway ties, fence and telegraph posts, hop and vineyard poles, and such purposes that the wood of the Catalpa is particularly adapted, and it is for these and similar employments, where a wood capable of resisting decay when exposed to the soil and weather is required, that Catalpa will probably be more profitably employed than the wood of any other tree suitable for cultivation over so large an area of the United States.

Why the soft wood of this fast-growing tree, which is traversed with large open ducts, nearly as broad as those of Red Oak—a wood which notoriously rots very quickly—should resist decay longer than almost any other of which we have any knowledge, is not clear. Many other similar instances of its power to resist decay are recorded. Another peculiarity of the Catalpa is its small amount of sap-wood or living tissue, so that, unlike the Red Cedar and most exogenous trees, in which the soft and worthless sap-wood turns by death into durable heart-wood only at the end of many years of growth, the Catalpa produces heart-wood when the stem is scarcely 1 inch in diameter. For this reason the Catalpa has not an equal for fence posts and different sorts of small stakes, for which, if other woods are used, many years of growth must be sacrificed in order to avoid the rotting away of the outer and living layers, which have no power to resist decay.

The few experiments which have been made with Catalpa wood for railway ties seem to promise that it will be of great value for this purpose, although such experiments are neither frequent enough nor of sufficiently long duration to be entirely conclusive; and it is evident that a longer test than it has yet been subjected to is necessary to demonstrate that this wood has the power to resist the crushing of the rails and to hold spikes equally well or better than Chestnut or White Oak, which, all things considered, are the best North American woods yet extensively employed for this purpose. It is but fair to say, however, that many practical railway men of excellent judgment, who are carefully watching in the West the Catalpa ties, speak with great confidence of their value, and already very large experimental plantations of this tree are being made in Eastern Kansas by railroad directors of that State, with a view of raising their own ties in the future. The Catalpa would seem, then, to be one of the most valuable trees which our cultivators, suitably situated, can plant. It grows readily and rapidly from seed, and can be very easily transplanted either in the spring or autumn. If planted thickly

say 4 feet between the plants each way—they will run up with tall straight stems, and make trees very different in appearance from the short-stemmed, round-headed, and rather distorted looking specimens which are met with in ornamental grounds, especially in the Northern States. The thinnings of a grove of Catalpa, if planted in good soil, will in a few years be large enough for vineyard stakes; in a dozen years the alternate plants will each make two or three fence posts, and the remainder will each, in twenty-five or thirty years from the time they were planted, probably be large enough to be cut into five or six railway ties. Cultivators to whom the annual expenditure for posts, fencing, or stakes is very considerable, will do wisely to plant every year a few hundred or thousand Catalpas, according to their circumstances, and thus ensure for themselves an abundant supply of home-grown material. Should the objection be raised that the planter of trees must wait too long for his returns, it must be borne in mind that the money value of land will be largely increased if it has upon it a thrifty growing grove of Catalpas.

A well-marked variety of the Catalpa is recognised in cultivation in some of the Western States flowering two weeks earlier than the ordinary form, which it is said to greatly excel in hardness, with larger white flowers and more upright, rapid growth. This variety reproduces itself from seed.

No. 807. SATURDAY, May 7, 1887. Vol. XXXI.

"This is an Art
Which does mend Nature: change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

EDITOR'S TABLE.

"Went out at early morning when the air
Is delicate with some last starry touch,
to make sure
At worst that there were Roses in the world."
ELIZABETH B. BROWNING.

SATINY STAR OF BETHLEHEM.—Charming in rooms—bold spikes and many satiny stars. Better effect in the house than out of doors—a very free-growing plant and hardy. Too free for some! A plant for the wild garden, where it may take liberties. Improves after cutting and placing in house; the stars become more open and whiter. Goes well with sprays of Portugal Laurel leaves. If there be no wild garden, do not plant it among or near any delicate alpine.

BUDDING LARCH TWIGS.—Very nice for table for first fortnight after showing green. Very fragrant; something like Mock Orange. Makes a pretty bunch if twigs with new bright cones and old cones are chosen.

SWEET BRIER SHOOTS.—Always delicious in rooms either with or without flowers—on cold, east-windy days seeming grateful to be brought into a room.

SCARLET WINDFLOWER.—The Pan form of this best for rooms because of softer colouring. It has the good quality, even if picked with the flowers closed for want of sun, of opening when brought into a warm room. It yields many flowers for cutting during several weeks.

DAY LILY LEAVES.—A tuft of the strong-growing orange Day Lily should be grown in some corner for the sake of its leaves for cutting. The whole leaf-stem cut just above the ground goes very well with flowers in the house.

JONQUILS.—The common Sweet Jonquil, a good flower for the table day or night. Stars very pretty in form. Odour pleasant and not too strong. Arranges well with tinted leaves and flowers of common evergreen Barberry.

DOUBLE JONQUIL.—A beautiful old plant, good for cutting and pretty on the table. Pretty in established tufts, but too rare in gardens.

DOUBLE DAFFODIL SULPHUR PHOENIX.—The prettiest and best of all yellow-tinted double Daffodils; beautiful in colour, better in a room than out of doors, where the weight of the head causes it to droop. Lasts well in a cut state; colour between primrose and buff. A form of the Nonsuch Daffodil, and the prettiest in colour of its double forms.

THE GOLDEN FRITILLARY (F. Moggridgei).—A large golden bell with brown dots inside and out—a singularly beautiful spring flower. One wishes to see enough of it to judge of its effect. What a beauty, dotted through Grass or Moss, this would be! I hope there is plenty of it somewhere. From Lady Ardilaun, St. Ann's, Clontarf, who also kindly sends other pretty

things, among which, more interesting for the table, are the following:—

THE WILD TULIP.—This neglected Tulip seems to me of great value in a cut state; its graceful way of opening and closing makes one take a fresh interest in wild Tulips. Its good colour and form should make it useful to hardy flower lovers, more so than many of the varieties and hybrids.

HOOP-PETTICOAT NARCISSUS.—Glad to see this so strong from Clontarf. I have no doubt it will have as graceful a use in the house as other bold Narcissi. The white Narcissus William Goldring is really a very graceful large flower, beautiful for any work. The Gentians—the vernal and the large Gentianella—opening a little earlier at Clontarf than about London; the Grape Hyacinths recently spoken of; the Persian Iris, exquisite in its delicate colour.

THE CYCLAMEN-FLOWERED NARCISSUS.—A lovely little form to have near one in a glass. With a profuse growth of hardy flowers in the open air, and in woods and shrubberies, the old and natural prejudice of gardeners against cut flowers will and should disappear. When one had only a small parterre or a greenhouse or two to cut from, it was necessary to be careful. Many hardy flowers are much more beautiful in form than those from the greenhouse. It will be a great gain to have these fine forms near the eye, and fresh flowers almost daily.

CLEMATIS MONTANA.—The beauty of this old-fashioned climber needs no extolling from me, as it clothes the walls of cottage and mansion alike with a sheet of the loveliest of white blossoms, and for covering arches, arbours, or anything where climbers are needed, there is really nothing likely to surpass it. I do not remember having seen it grown under glass before. The spray enclosed is from a cold house, but it is nearly a month in advance of the outside plants. The reason for planting it under cover was from having a demand for white flowers all the year round, and finding this Clematis, when in bloom, one of the very best for wreaths, I decided to try and get a longer supply than can be had from the usually sunny walls of the south coast, so I put a plant in a cold greenhouse (from which the enclosed spray is cut), and another on the darkest north aspect that I have, and from these plants I get a longer supply by several weeks. Many try to grow plants in a cold house that really require heat, and thereby court failure; whereas if they took hardy plants, and just gave them the shelter of a glass roof, they would be amply repaid. Many gardeners who know this old Clematis well, say, on seeing it under glass, "Well, what new thing have you here?" thinking it was some new Clematis, and have been rather surprised to find an old friend put to a new use.—*J. GROOM, Gosport.*

CARPENTERIA.—Flowers gathered from back wall of a cool greenhouse, where the effect of leaf and flower is very beautiful, plant covering wall. Flowers charming in lamplight. A grateful and delicate odour, like Larch in its first week of buds.

OXLIPS.—Very bold and handsome, from Mr. Hartland, of Cork. I often see the wild ones on the fringes of woods, and am struck with their beauty, and wonder why they are not more cultivated. One that Mr. Hartland calls William of Orange is a singularly good, bright

plant, and so is the paler Danesfort Sulphur, which is a kind of Hose-in-hose. He also sends a rich Irish Hose-in-hose Polyanthus and the crimson Hose-in-hose, nice old flowers, but certainly not so good as the handsome William of Orange.

STOVE AND GREENHOUSE.

T. BAINES.

THE CAMELLIA HOUSE.

CAMELLIAS have been plentiful and very fine this season. We have had an unlimited supply from Christmas up to the present time, and they will last nearly to the end of May. All the varieties have done well, the very best, so far as abundance of flowers is concerned, being the old French White, alba plena, Lady Hume's Blush, Marchioness of Exeter, and Woodsii. I cannot help thinking that a small Camellia house should find a place in all gardens of any size, as a great quantity of bloom can be cut from a comparatively small structure when the plants are well established, and this, too, with very little labour or expense. The treatment of Camellias after the flowering season, from the end of May until the following Christmas, will naturally depend in a great measure on the age and condition of the plants. In our own case, with plants that have been in their present quarters over half a century, it may be summed up in a few words—viz., a good thinning out of the wood about the latter end of May, a liberal top-dressing at the same time, plenty of water and plenty of air. Where there is abundance of space at command, the knife may, of course, be dispensed with; but where the plants are at all cramped for room they must be kept within bounds, and if the growth is dense and luxuriant this cannot be wholly effected by tying in. Some varieties, as Lady Hume's Blush, Cup of Beauty, &c., are rather impatient of the knife, but with strong growers I generally remove rank, forward growth, together with any spindly stuff, reserving the hard, sturdy back shoots for another season's bloom. No shade of any kind is used at any time throughout the year, and I have never noticed any scalding, except, perhaps, on one or two tender shoots that may be close up to the glass. The wood under these conditions gets thoroughly well ripened, one of the essentials to the production of plenty of fine flowers before the approach of autumn. After all pruning and tying in is finished, a top-dressing of cow manure is put on all over the beds, from 2 inches to 3 inches in depth, and copious supplies of water are given at intervals of ten days all through the summer. The house is fumigated occasionally through the summer to check any fly that may make its appearance, and has a good syringing once or twice a week during the hot weather, the foliage at these times having a thorough drenching with the garden engine. A little extra care is required after this to prevent any scalding in the early morning, but if a hot, dry evening, with, if possible, a slight wind, be selected for the operation, the foliage will be dry before the sun has any power on it. Disbudding is attended to at the proper time, at intervals of a week or ten days. It is invariably our practice to leave about three buds on each shoot, about 2 inches or 3 inches apart; this ensures a succession of flowers, and, in addition, admits of a little wood being cut with the bloom when this is necessary. I have been cutting on an average 60 dozen per week for the past two months.

E. BURRELL.

Weigelas forced into bloom.—The common *W. rosea* will expand its blooms in a very satisfactory manner when forced, but is seldom treated in this way, though when in full flower it is a worthy companion to the many flowering shrubs whose season of blooming is hastened on by a little gentle forcing. One point with regard to the Weigela is that it seldom blooms freely when small, and on that account can only be relied upon for indoor decoration in the form of fair sized bushes, which should be grown in an open position fully exposed to the sun in order to thoroughly ripen the

wood. Besides *W. rosea* there are *W. Abel Carrière*, whose blooms are finer than those of the older kind, *W. candida* and *hortensis nivea*, both white, but widely different from each other, the first being upright in habit, while in growth the other is spreading, and the leaves are larger and more rugose. Of the two, *W. hortensis nivea* seems the easier to force. Among deeper coloured kinds, which, however, are by no means so effective under glass as those above mentioned, may be noted *Lavallei*, *Beranger*, and *Emile Gallé*. All the *Weigelas* have long been recognised as beautiful outdoor shrubs, but their value for conservatory decoration has been to a great extent overlooked. They may all be struck from cuttings or raised from seed, which in a warm spot ripens in abundance. In the case of seedlings I found that there were several inferior to their parents.—H. P.

PLANTS FOR HOT, MOIST WALLS.

THE number of climbing plants that require the temperature of a stove is very great, but the list of those that will clothe a wall with foliage and at the same time attach themselves thereto without constant attention in the matter of tying or nailing is by no means extensive, yet there are a few well suited for such a purpose, and as they will thrive even where heavily shaded, are thus rendered additionally valuable. The back or end wall of a hot-house is a good place for them, for though in the lighter places a wire screen may be put up, filled with peat, and then planted with Ferns, foliage Begonias, and such things, yet where heavily shaded many subjects will refuse to grow. Of plants that need no preparation in this way, as they secure themselves to the wall by means of their aerial roots, the best include a few Aroids and two or three species of Ficus. One of the finest of all plants for such a purpose is *Pothos celatocaulis*, rather a quick-growing climber, with very deep green, oblong-shaped leaves about 5 inches or 6 inches in length. These leaves are tightly pressed to the wall against which they grow, and are arranged so closely together that they slightly overlap at the base. Another plant with the same habit is *Maregravia paradoxa*, with roundish, unequally-sided foliage in its juvenile form, for this *Maregravia* occasionally grows out of the above character, and the stem thickens greatly, when large divided leaves, something like those of *Monstera deliciosa*, are produced. This character, however, does not appear to be very common, so that for general purposes the simple closely-fitting leaf may be regarded as the normal form. *Maregravia dubia* is another of this class, with smaller leaves, much narrower in outline, but disposed as regularly on either side of the stem as the ribs in the skeleton of a fish. The next (*Scindapsus pictus*) attaches itself to the wall by means of roots from the stem, but the leaves do not press closely to the wall in the same formal manner as the others. The leaves of this are unequally-sided, in shape something like a Begonia, and marked with irregular blotches of greyish white on a dark green ground. The colour of its foliage renders this plant admirably suited for planting in such a manner that it will grow and intermix with the above-named dark-leaved kinds. *Philodendron melanochrysum*, with deep olive-green leaves, overlaid with a satiny lustre, is very pretty. The colour of the foliage will only apply to the adult leaves, for the young ones are lighter in tint and have the satiny character still more pronounced. *Pothos aurea*, with the leaves more or less marked with gold, promised to be a very desirable subject for such a purpose when first sent out, but it rapidly developed into a coarse-looking plant, and in most cases almost lost its variegated character. The small-growing *Ficus repens* and variety (*minima*) are first-rate wall plants, for they attach themselves with great tenacity to brickwork that is kept moist. The stronger-growing *F. radicans* is also available for the same purpose, its style of growth being more rapid and less formal than in the other two. *Piper Futokadsura* is a Japanese species of Pepper, with dark green heart-shaped leaves, a good deal in general character like a *Philodendron*, but, in common with the above-named kinds of *Ficus*, it will thrive

in a greenhouse temperature. In order to encourage aerial roots, the surface of the wall must be occasionally moistened. All the plants mentioned above are of the easiest possible culture, for even if branches cannot be separated with roots already formed, they quickly strike when placed under favourable conditions. Insect pests, too, do not trouble any of them, and as they are so fond of moisture, the leaves can always be kept clean by liberal syringing. T.

SPECIMEN CARNATIONS IN POTS.

I AM unable to endorse all that has been said in favour of the Carnation as a winter-flowering plant, as I consider that the number of flowers they produce is a very inadequate return for the labour they involve when grown as single plants. So far as I have seen or read, the placing of half-a-dozen plants in a pan of a suitable size is quite a new departure. This mode of growing the Carnation has been practised in a garden in this county for three or four years past, and with the most satisfactory results. The pans were specially made for the purpose, being 6 in. deep and varying in diameter from 12 in. to 18 in. Only one variety was grown in a pan, as Carnations differ a good deal in the character of growth as well as in height of flower-stem. Having seen the stock grown in this way on several occasions, I have no hesitation in saying that not only do the plants grow and flower better, but they are more effective, and are very suitable for the front bench of a light and airy conservatory. When seen growing in this way, that leanness of appearance of a single plant in a pot is got rid of, as more growth and a greater number of flowers are brought into a smaller space than is the case when they are grown in the ordinary way. With regard to other details of management, the plan followed in the case alluded to was to strike the cuttings on a gentle bottom-heat early in the year, and as soon as they were sufficiently rooted they were placed in the pans in which they were to flower, and until they got well established they were placed in a vinery from which frost was kept out until about the middle of April, when they were transferred to a cold pit. In this structure they got more air, and as the spring advanced the lights were removed during the day when the weather was suitable. My friend assured me that he placed more reliance on securing an early growth and a suitable soil than anything else, and that he never pinched out a flower-spike after the middle of June. If any felt disposed to flower after that they were allowed to do so. What he appeared to aim at was to get a vigorous growth without subjecting the plants to a close-heated atmosphere.

By giving abundance of air, the growth is sufficiently strong to bear a strain that will successfully carry them through the depressing influences of a long winter. If there is one other feature in the management that should be mentioned, it is that the stock is not exposed altogether in the open until the plants have made good growth, all weakly ones being kept in the frames all the summer. Another point of interest is the Carnation's love of sunshine, as the stock is never shaded after the plants have become established, and when they are turned out of doors in the summer it is in a position in the full sun, with the pans standing on a hard bottom to prevent worms entering them. The question of providing a suitable soil for winter-flowering Carnations is, I think, of the greatest importance. I find that they have a dislike to a heavy root-medium, therefore it is not desirable to use more than half loam, to which should be added one-fourth each of peat, leaf-soil, and sand. A mellow sandy loam will, I am aware, grow them well with no other ingredient mixed with it; but loam varies so much in its composition, that if used in larger proportions than one-half, much of it is altogether unsuitable where an open medium is required for a considerable time, and Carnations, not being strong-rooting subjects, cannot endure any excess of moisture in the soil. J. C. C.

Amaryllis marginata conspicua. For general decorative effect this *Amaryllis* is one of the best. Its constitution is good, while the spikes of bloom

are freely produced; the flowers, four and five on a stem, are striped with white on a rich crimson ground. We find the plants do well stood on slates over the evaporating troughs in the Melon house, potting them and starting them into growth towards the end of January. When well rooted they are freely supplied with liquid manure until the plants are in flower. After they have flowered the plants are stood on a shelf in the vineries close to the glass, where they make free growth.—E. M.

Eucharis amazonica.—I think the finest lot of specimen *Eucharis amazonica* I ever saw is at Gammersbury Park, Acton. There are about a dozen or so of specimens in the most healthy and vigorous condition in No. 2 pots, and they have not been repotted for nearly two and a half years. At the time they are flowering they are liberally fed with soot water and liquid cow manure, and they throw up large trusses of very fine and handsome blooms. Mr. Roberts states that the secret of growing *Eucharis* is that when a young leaf comes up a flower-stem will be sure to follow, and as soon as the young leaves appear the plants should be dried off and the flower-stem comes up. Mr. Roberts evidently proceeds upon the principle of growing his *Eucharis* in more heat than is generally the case, and to this he attributes his success. He keeps his plants in the house in which he grows his East Indian Orchids, and they measure from 5 feet to 6 feet in diameter. The number of flowers they supply is almost incredible.—R. D.

Sea sand for plants.—My experience with sea sand is entirely at variance with your correspondent's. Two years ago, falling short of silver sand, and residing within a few minutes' walk of a beach largely composed of sand of all "grades," which may be had for taking away, I sent for a load and used it throughout the potting season. The result was that most of the plants suffered from its effects; many died, others survived, but have not yet wholly recovered; in fact, very few, indeed, bore it unharmed; even such robust things as *Strelitzias*, *Caladium esculentum*, and *Bruguansias* suffered severely, and are still sickly. The effect was in all cases alike; black blotches appeared on the stems and leaves, where rotteness set in afterwards. I suppose the salt was taken into the circulation. But the same material, passed through three or four waters, answered the purpose without any injurious consequences. J. M., *Charmouth, Dorset*.

Clematis indivisa. This *Clematis* has flowered most profusely with me this season in a cool conservatory, trained thinly close to the glass. Where its branches have full light and sun, the wood becomes thoroughly ripened, which is the principal cause of success in flowering this lovely *Clematis*. Now is a capital time to attend to such plants for their future welfare. Should the last season's growth have become in any way too thickly entangled, remove entirely some of the weakest branches, tying those remaining thinly to wires stretched to the rafters, and top-dress the plant by removing some of the old surface soil down to the roots, replacing this with some turfy loam, leaf-soil and bone dust, and when growing freely give copious supplies of liquid manure. Vigorously syringe the foliage in the evening after a hot day, and attend to the tying in of the young growths before they become laced together. Mildew sometimes attacks this plant in the spring. For this evil apply flowers of sulphur dusted over the parts affected. E. M.

Aloe plicatilis.—At the present time a remarkably fine specimen of this plant, measuring 8 feet high and 9 feet wide, is now in bloom in the succulent house of the Botanic Gardens, Cambridge. The flowers, which are just beginning to expand, are red tipped with yellow. The base of the plant just above the surface of the soil is 5 feet in circumference, and directly above this it branches out into three spreading stems. About a year ago it was retubbed. The results of this shift may easily be recognised by the extra strength and length of the foliage. The compost used was good yellow loam, with a proportion of coarse sand and broken pieces of soft bricks well mixed together. Aloes are rather slow growers, and the above specimen must be a considerable age. Growing in the same house is a

much smaller plant, a variety of the above called *majus*, which is extremely handsome. It has more robust foliage and single branches, and resembles a large fan spread open. These plants thrive best in a temperature where frost is excluded.—W. H.

SUCCESSSES OF A SMALL GREENHOUSE.

I HAVE for nearly twenty years been the owner of a small greenhouse, of which I am not a little proud; it is only 20 feet long by 12 feet wide, and yet I have managed to grow in it more things than some people would think possible, and some which are not ordinarily considered easy in so small a structure, and I think that perhaps a few notes on some of these may not be unacceptable to the readers of THE GARDEN, especially as I see frequently questions are asked concerning some of them.

DISA GRANDIFLORA.—I have had a long acquaintance with this, the most beautiful of terrestrial Orchids, since my late friend Mr. Charles Leach, of Clapham Park, who first flowered it in 1861, gave me a small piece of it. This I lost after two or three years, owing, I believe, more to the bad quality of the peat used than from bad management. About a dozen years ago I obtained a nice clump of it, and with this I have been most successful. Last year I had two pans of it; one about 9 inches across had ten flowering stems containing twenty-six flowers. The variety is that called *superba*, and is the brightest of any I know. Last autumn, after it had done flowering, I had to separate it, as I wished to give pieces to some friends. I was told that it delighted in being pulled to pieces, but I have not found it so. I have now four pans of it, but I shall not have such blooms as I had last year, and I much doubt the statement that it likes being pulled to pieces. When dividing it I left one clump untouched—that is, did not divide it, and potted it separately, and this is the strongest piece I have. When the advice was given to pull it to pieces, I fancy the writer's experience had been with what is known, I believe, as the *Glasnevin* variety, which seems to me more robust, but very inferior in the quality of its flowers. Mr. Burbidge kindly sent me a piece of this to compare, but I question very much whether I shall care to increase my stock of it, and in dealing with my own plants this autumn I shall simply take out a large portion of the peat and replace it with fresh. As I have before said, this Orchid is as easy to grow as a scarlet *Pelargonium* if people will only attend to simple rules, but that is the difficulty; being an Orchid, they think it must require heat, whereas really the less it has the better. In winter I simply keep it where frost will not reach it, and in the spring remove it to the shelf nearest the door of my house. It is potted in good peat, with lumps of charcoal. Some advocate *Sphagnum*, but I have never used it. It is always kept moist, and when growth commences in earnest I syringe it twice or three times a day. With this treatment it is sure to do well.

LAPAGERIA ROSEA AND L. ALBA.—It showed, as I was told, some considerable courage to attempt these somewhat rampant climbers in so small a house, and I was warned that if they grew they would certainly shade and injure the other inhabitants of the house. However, I determined to try; and as my house runs east and west and is a span-roof, I planted them in two large pots and placed them at the east end. They grew and flowered well, but two years ago I found it necessary to give them more root-room, so I had a box made, which fitted on the platform in the middle of the house at the east end. They were planted in this, and have done uncommonly well. Last year I had, I should think, a hundred blooms, and although this is child's play to those who have large spaces at their disposal, and even houses devoted to them, yet it may be an encouragement to smaller men to know that they can be thus grown. I have found *alba* the sturdier of the two. There is one thing that has to be carefully guarded against—the depredations of slugs, who, if they possibly can, will find out the young shoots and eat them clean across. When the days begin to lengthen and the sun to acquire power, I nail a piece of shading over the end of the greenhouse where they are, so as to give them the

shade they delight in; they are also during the spring and summer well syringed.

MARECHAL NIEL ROSE.—Some years ago I placed a plant of this in a large pot in the small lean-to which I have annexed to my greenhouse, and in which is a Vine; it grew so well, that I trained it to the back wall of the house. It has gone on increasing from year to year; the roots have pushed themselves through into the soil, and it has completely covered the wall. Last year I cut about 150 blooms from it, and this year shall probably cut more. The plant is as healthy as can be, and has evidently got into something that it likes; and although the blooms are not so highly coloured as one could wish, they are excellent, with good stiff foot-stalks and fresh green foliage. As to the deep colour which this flower sometimes exhibits, I should be glad to know how it is produced, although my experience of a reply to this is not much in favour of getting a satisfactory one. I was standing the other day at South Kensington by the beautiful golden blooms exhibited by Mr. J. Walker, of Thame, and made use of the expression, "I wonder how they get so rich a colour!" There were two or three *Rose* growers standing by. "Oh!" said one, "evidently by shading." "Not at all," said another; "I believe it is by being in bright sun." When doctors disagree, who shall decide? At any rate, I have had great pleasure in my plant, and can safely contrast its brilliant green foliage with the yellowish green of some other plants I see elsewhere. It gives me all its flowers before the Vine shoots are any length, and, as it is in a warm position, ripens its wood sufficiently. When I first had it I had no idea of keeping it so long, but thought that perhaps after a year or two it would have spent itself, and I should have had to throw it away; but it has improved every year, and I hope to retain it for some time to come.

FREESIA REFRACTA ALBA.—At one time this was considered a difficult bulb to grow, and its specific name was thought to be in reference to its refractory character! It has, however, proved itself amenable to culture, and this season I have had it very fine. They were planted six in a 5-inch pot, and the plants grew to from 15 inches to 18 inches high, and although each bulb threw up only one flowering stem, yet this had four flowering shoots, and so vigorous were they, that this observation was made concerning them—that the pots were too crowded with bloom. As I know some people still complain of a difficulty in growing them, I may say that I believe one element of success is to thoroughly roast the bulbs after the flowering season is over. I place the pots on a top shelf near the glass, and leave them there until thoroughly dried off; they are then removed and laid under the stage until the time for potting comes round; but had I the convenience for doing so, I should keep them in the same place all the summer. They seed freely, and if it is wished to save seed they must be treated differently—water must not be withheld, and they must not be placed in quite so warm a position. It is very satisfactory to find that this most fragrant flower is so easily managed, for, both for its beauty and perfume, it is invaluable for cutting.

PRIMULA ORCONICA.—This, I think, is the most remarkable plant for continuous blooming that I have ever seen; the two plants I have of it, which came to me from my friend Mr. Lewelyn, have now been in flower for twelve months—by in flower I do not mean a spike or two, but a dense mass of flowering stems, making quite an effective head of bloom—and on examining it to-day I see quantities of fresh trusses showing themselves in various stages of development. Is there any other flower that acts thus? Its treatment is simple enough; it requires, I think, tolerably rich soil, but not to be over-potted, must have plenty of drainage, and then, like most of the *Primulas*, it enjoys plenty of water. DELTA.

Lachenalias.—These plants are popular favourites, and are very useful in the greenhouse or conservatory, as they remain for a long time in flower. They are usually grown in pots, in a com-

post composed of peat, loam, leaf-mould, and sand with some charcoal broken in small pieces. They must be placed close to the glass. For growing in baskets I know of no other greenhouse plant to equal them. We have had them in the same baskets without disturbing them for the past two years. Before planting them we line the baskets with turfy loam, pulled to pieces and the dust shaken out, and when the bulbs show signs of growth they are placed in the interstices of the wires at a distance of every 2 inches or 3 inches apart, and also over the surface of the basket. They are never allowed to become dry after they have once commenced to grow. For the past two months they have been in full beauty, the framework of the basket being completely hidden by an abundance of luxuriant foliage and flowers.—W. H.

SPRING NOTES ON THE AURICULA.

THE exhibitions of Auriculas are now over, and, writing from my own experience, I have to say it is a time of careful preparation for next season. When plants are required to be in their best dress on a certain day they have either to be forced or retarded, and the Auricula is impatient of either treatment. Everywhere it has been necessary to put pressure upon them; nowhere has it been necessary to keep them back. The result of artificial heat or a close atmosphere is to cause the leaves to become rather flaccid, but as soon as the show-day is over the treatment is reversed; more air is admitted to the plants, and no artificial heat is allowed. When the weather is fine the lights are removed altogether; but it must not be done in high winds, nor ought the plants to be exposed to rain. Give the choice varieties as much space as it is possible to afford them. If no seeds are to be saved, preparations must be made during May to repot the plants; but see first that they are quite free from greenfly; and the best way to destroy this troublesome pest is by fumigating.

The pots used for the plants must not be too large, and if they have been used previously, wash them clean and place a fair proportion of drainage in the bottom. The best potting soil is good decayed turfy loam four parts, one of leaf mould, one of manure, and some sharp silver sand. Before repotting any of the plants examine them carefully for the Auricula aphid (*Triana auriculae*); this pest must be destroyed if possible. When the plants are repotted, place them in a frame on the north side of a wall or fence, as being the best place for them. The small offsets and seedling plants should also be potted on as they require it. Offsets taken from the parent plants last summer will be the best to flower next year if they are carefully attended to.

THE CARNATION AND PICOTEE.—I would like to allude first to the seedlings planted out in the open borders; not a single plant has been killed by the frosts, that is, the seedlings which have not yet flowered. Older seedlings that flowered last year and were not layered have suffered considerably. We keep up a constant succession of these interesting plants. The seeds were sown over a hotbed about the first week in April. About 700 plants have been already planted out in boxes from the best crosses. My plan is to select a different section of the Carnation or Picotee each year, instead of spreading the experiment over the entire field. For instance, this year I am dealing almost exclusively with the yellow Picotee. The white ground varieties have not been touched, but I would only deal with one of the sections, if they were taken up next year, and even then the field is wide enough. I would take the red-edged section, which in itself contains a broadly marked division in the light and heavy edges. The best of the red-edged type would be, in heavy red, John Smith, J. B. Bryant, Brunette, and Princess of Wales; place plants of all these together, and use the pollen brush indiscriminately amongst them. Place together of light red-edged varieties Mrs. Gorton, Thomas William, Emily, and Dr. Homer. It is not to be supposed that all of the seedlings will produce red-edged Picotees, or Picotees at all; in fact, our finest self Carnations have been produced by crossing Picotees with each

other. After the above slight digression, I will return to the Picotees pricked out in boxes; they will be planted in the open ground about June in good, deep soil. Careful cultivation subsequently will produce good substantial plants by the end of the season, and the quantity of bloom some of them will produce is astonishing. I have counted over 200 flowers on one seedling treated as described above. The named plants in pots are still in frames; they are quite a month late this year, but they soon gather strength when hot weather sets in. The surface of the soil in pots may be treated to a dressing of rich compost—loam, leaf-mould, manure, and sand in equal proportions. The plants will be turned out of doors as soon as fine weather sets in.

PANSIES are now coming into bloom; the plants were wintered in a cold pit, close together in boxes. In February or early in March they were replanted further apart again in boxes to be planted out about the middle of April. The soil is deeply trenched and made rich with a liberal dressing of decayed manure, as the plants spread very much in summer, entirely covering the ground. Seedlings grow more freely, and make even a better display than named varieties. The seedlings do not require any glass protection during winter. The time for planting them out is early in October from seeds sown in August. J. DOUGLAS.

Passiflora kermesina and **P. princeps**.—To those in quest of stove climbers with beautiful flowers, and, at the same time, of easy cultivation, I would recommend the above. *P. kermesina* is now bearing in profusion its rich carmine flowers in one of the stoves at Gunnersbury Park. It is growing in a 10-inch pot, and trained along the roof displays its wealth of bloom very effectively. *P. princeps*, with its rich carmine-scarlet flowers, is also very effective treated in the same way. W. T.

Bougainvillea spectabilis.—I forward you a few sprays of *Bougainvillea spectabilis* to show how freely it flowers when the conditions are favourable. The plants from which the sprays are taken are grown by Mr. Rogers, Frimley Park, Surrey, and occupy a position in an intermediate house, trained to wires and fully exposed to the sun, and seldom fail to flower satisfactorily. *B. glabra* grows luxuriantly and flowers freely planted out in the same house.—E. B. L.

* * The sprays sent well bear out the remarks of our correspondent. We have seldom seen the flowers so rich in colour and on such strong footstalks. The foliage, too, is remarkably bright and handsome, the tips of the leaves being as highly coloured as the flowers. When seen in a mass, it is truly a grand sight.—ED.

SHORT NOTES.—STOVE AND GREENHOUSE.

Melon Pear.—What is the botanical name of the above, offered this year by one or two seedsmen? It looks like a *Solanum*, but I have not seen it in flower.—J. M.

Soot for Azaleas.—Will any of your correspondents kindly inform me as to the best way, and at what strength, to apply soot to Azaleas making their growth?—G. S. W.

Seedling Tree Carnations.—I send you blooms of two seedling Carnations, and shall be glad of your opinion regarding them.—T. ASH.

* * The blooms sent are no improvement on existing varieties.—ED.

Salvia Bruanti.—*Salvia* are grown well at Frimley Park; some fine plants of *S. Bruanti* are now in full beauty. This variety is much superior to the old *Salvia splendens*, the growth being more compact, and producing a much finer spike of flower.—E. B. L.

Double-flowering Pelargoniums.—I send you a box of *Pelargonium* flowers. Kindly say in your next issue what you think about them. They were cut from plants from which we have been cutting all the winter, and we could not as many as thirty trusses from some of the plants at this time.—G. H. MOTTSON.

* * The trusses received were large and of a fine colour. They consisted of pink, white, scarlet, and salmon varieties—altogether very pretty and bright.—ED.

Pepino and Curuba.—Why are not seeds of these seemingly valuable plants to be obtained in England? The Passion Vine referred to seems to me a precious treasure, quite suitable for cool houses in this country, and, therefore, almost everybody's plant. It is a pity that nurserymen do not direct their attention to such things instead of the hosts of tropical plants that so few comparatively can possess, or, possessing, successfully cultivate. Will M. Gustave Eisen attend to this? I, for one, would gladly pay for some seed.—J. M., *Charnooth, Dorset*.

SEASONABLE WORK IN PLANT HOUSES.

STOVE.—TRAINING AND TYING.—The rapid growth which healthy, well-managed stove plants make is such that constant attention to training and tying at this season is requisite, without which the shoots of many kinds get so entangled that they cannot afterwards be separated without injury. Climbing and twining plants, such as *Allamandas*, *Dipladenias*, *Bougainvilleas*, *Aristolochias*, some of the *Thunbergias*, and others of like habit, are now much oftener grown in pots as trained specimens than they used to be when the roof or rafters of the stove were the positions usually assigned to them, and where, unless their number was much restricted, they formed a thicket that excluded the light too much from the plants in the house. But when the plants in question are grown in specimen form, it is particularly necessary that they receive close attention in regulating the shoots, keeping the extremities, as advised some time back, well up, for if bent down, or allowed for want of support to hang down until the flower-buds are set, the plants will bloom sparingly, or not at all. The flow of sap, in place of being directed to the extremities of the shoots in the way it would if they were in an erect position, expands its force in pushing the lateral eyes. Through keeping the young shoots constantly trained down, I have seen specimens of *Allamanda* and *Dipladenia*, otherwise well managed, that scarcely produced a decent spray of flowers during a whole season. Where there happens to be a conservatory that is kept at an intermediate temperature, specimen stove plants of many kinds will do good service for many weeks in the summer, as if too much external air is not admitted they will then keep on blooming in less heat than is needed to bring them into flower. Most of the *Ixoras*, for instance, though requiring as much heat as any plants to grow them well, will keep in good condition for a month in a temperature such as that just named. In no way can such plants be turned to better account, as they afford variety to the ordinary occupants of a conservatory, and this at a time when there is comparatively little in the shape of flowering plants available.

SHRUBBY CLERODENDRONS.—The different kinds of shrubby-habited *Clerodendrons*, such as *C. fallax* and *C. Kempteri*, are most useful for ordinary decoration when in the form of small examples confined to single stems, such as are obtainable in plants struck from cuttings last summer, or raised from seed sown as soon as ripe. Plants raised in this way will now be making vigorous growth, and will soon show their flower-spikes. They should not be stinted for root-room: 12-inch pots are not too large to give the heads of bloom a chance of attaining their full size. Where larger pots are needed, it is not too late to give them a shift, being careful not to disturb the roots in the removal. The double variety of *C. fragrans*, although now seldom met with, is worth growing for its distinct and agreeable perfume. It occupies comparatively little room, as the stems are best cut down to the bottom after flowering. It is a Chinese plant, and does not require quite so much heat as most of the other species; it will produce two crops of flowers in the season, the first coming in spring, the second in the latter part of the summer. With this kind it is better to grow several medium-sized examples than to confine the stock to a few large specimens, as with a little management in regulating the time of flowering, a succession can be had. The flowers, when mounted two or three together, are very useful for bouquets and button-holes, whilst a small plant will scent a large house. It strikes readily from cuttings, suitable materials for which are usually present in the weaker growths that spring from the collar of the plants, and which are not strong enough to flower. These, if taken off now, will root readily with shade and moisture in a brisk heat. With the requisite attention afterwards in growing them on through the summer, they will make useful flowering plants next season.

EUPHORBIA JACQUINLEFLORA. Some growers find this fine winter-blooming plant difficult to manage in several ways, whilst in the hands of others it grows as freely as a weed. Results so different can only be accounted for by assuming

that those who fail with the plant do not realise its peculiar requirements. To grow this *Euphorbia* properly it must be pushed along in a brisk growing heat from the time the cuttings are struck. It likes a temperature as high as most stove plants; it must be kept close to the glass, lowering the shelf, or whatever the pots are stood on, as more head room is required. Unless it is desired to grow the plants in bush form, it is better not to stop the shoots at all, simply letting them grow as high as they will. As a rule, the taller they get the stronger they will be found. From the time the young plants are established and have begun to grow freely, they like to be regularly fed with manure water given at a moderate strength. Scarcely any plant that I know requires so little pot room; if supplied with manure water in the way suggested, a 6-inch or 7-inch pot will be large enough for three or four plants. They do quite as well thus grown together from the cutting pot onwards as if potted singly. Another important matter is to be careful never to over-water; the roots will not bear the soil being too wet. The plant likes a moist atmosphere; consequently air should not be admitted in such quantities as will dry the air of the house too much. A thin shade is necessary in bright weather. It is well to shut in plenty of sun heat by closing early, syringing overhead at the same time. Towards the end of summer more air should be given, but enough heat ought to be kept up to maintain free growth. Treated in this way this most useful winter bloomer rarely fails to answer.

WINTER-FLOWERING BEGONIAS.—The amount of bloom which this section of *Begonias* is capable of producing in a great measure depends on the size and strength the plants attain. To get them up to the requisite condition they should be pushed on early in the season by giving sufficient warmth to keep the growth moving freely. As the soil gets full of roots give more pot room, regulating the size of the pots in accordance with the size and strength which the kinds grown naturally attain. Repeat the shoot-pinchings sufficiently often to secure the desired bushy form. Stand well up to the glass, and afford enough room to prevent any inclination in the plants to become long-jointed. Shade is necessary in bright weather, though the foliage of all the *Begonias* is less impatient of the sun's direct rays than some things. Later on, when the plants are in the pots they are to flower in and the roots have got well hold of the soil, manure water should be given every week.

GREENHOUSE.—SPARMANNIA AFRICANA.—This distinct, free-growing plant is alike adapted for growing in a moderate-sized greenhouse or a large conservatory. In a structure of the latter description half-a-dozen good specimens are very effective when in bloom, the time of which depends much on the temperature the plants are kept at. Grown cool they will generally bloom in April or May. Plants that are now blooming may have their shoots cut well back as soon as the flowers are faded; but if the knife is not used further than to remove the old flower-stems, the plants may be expected to push growth that will bloom towards the end of summer. Cuttings should now be put in, or as soon after the flowering is over as suitable shoots can be obtained. They are best put singly into little pots. The plant is a strong, quick grower, rooting freely; consequently it requires to be liberally treated. When the cuttings are well rooted they may be placed in 5-inch or 6-inch pots; good turfy loam with a liberal addition of rotten manure and some sand answer well for them in every way. Keep in a genial-growing temperature until the young plants get well established; during the summer a pit that admits plenty of light with a little shade in bright weather, and a moderate amount of air in the daytime, shutting up early whilst the sun is on the glass, using the syringe freely every day at the time of closing, will get them on so that they will require moving into the pots in which they are to bloom early enough to admit of their roots getting fully hold of the soil before autumn, when a drier atmosphere, more air, and no shading will prepare them for winter. Through this season the soil should be kept somewhat drier. T. B.

ROSE GARDEN.

T. W. GIRDLESTONE.

HENRI JACOTOT, RAISER OF GLOIRE DE DIJON.

UNTIL Henri Jacotot delighted the Rose growing world with Gloire de Dijon, there was no hardy climbing Rose of anything approaching yellow in colour. That a chance seedling should suddenly supply this want in every particular ought by itself to be sufficient inducement to all Rose growers to sow the contents of every Rose hep that they can lay hands on: for the fact unfortunately remains that the pedigree of Gloire de Dijon was not preserved, and its parentage consequently is not certainly known. The appearance of the plant, however, can hardly fail to give an impression of a strong Bourbon influence, and the late Mr. H. B. Ellwanger, of New York, expressed his opinion

known: but as long as a variety has qualities that commend it to every lover of Roses the raiser's name will be cherished, and certainly the name of Jacotot, rosarians will not willingly let die. As for the qualities of Jacotot's great Rose, it seems absurd to attempt to say anything fresh about a Rose that is already classical, and it will be impossible to do better, in concluding this brief reference to the raiser of the most popular Rose the world has ever known, than to quote the description of the greatest classic of Rose literature, Canon Reynolds Hole, who says of Gloire de Dijon:—

Its flowers are the earliest and latest; it has symmetry, size, endurance, colour (five tints are given to it in the Rose catalogues—buff, yellow, orange, fawn, salmon, and it has them all), and perfume. It is what cricketers call an "all-rounder," good in every point for wall, arcade, pillar, standard, dwarf, *en masse*, or as a single tree. It is easy to cultivate out of doors and in. It forces admirably, and you may have it almost in its summer beauty when Christmas snows are on the ground. With half-a-dozen pots of it, carefully treated, and half-a-dozen trees in your garden you

in Burgundy, and died there not many years ago.—Ed.

ROSES AFTER THE WINTER.

It is only when the Roses are pruned in spring that the actual amount of damage done by a severe winter can be clearly estimated; although, of course, it does not follow that even then all the injuries that have been inflicted will be apparent. Some of these occasionally will not become obvious until late in the season; but, as a rule, it is possible at pruning-time to obtain a comparative estimate of the condition of a large majority of varieties. Considering the long spells of cold to which plants out of doors were exposed during the late winter, when on two successive nights there were registered 25° of frost, it was inevitable but that the Roses should suffer to a greater or less extent, and, on the whole, it may be said that they have passed through the ordeal fairly successfully.

Among the Hybrid Perpetuals the greatest damage seems to have been done among the light coloured varieties, the darks in many cases being very little injured; and taking those that were hardest hit more or less in order, the list is undoubtedly headed by Madame Prosper Laugier, which had the pith discoloured, or was killed to the ground-line in almost every instance. All the Baroness Rothschild group, including also Merveille de Lyon, White Baroness, and Mabel Morrison, suffered severely, as did all the most beautifully tinted rose colours, such as Marie Finger, Eugénie Verdier, Pride of Waltham, Countess of Rosebery, Lady Sheffield, and Constantin Petia-koff. The last-named, of course, one always expects to lose, but it is none the less to be regretted that these lovely coloured Roses are not more capable of withstanding a hard winter, and there is ample work for Rose-raisers for some time to come to produce a Countess of Rosebery as hardy and vigorous as Ulrich Brunner. La France and Duchesse de Valombrosa were both discoloured a very long way down, but are breaking strongly from the base, and the same may be said of Comtesse de Serenye and Madame Lacharme. Two Roses of widely differing types in Etienne Levet and François Michlon were desperately cut up, the latter especially, almost more so than Madame Charles Wood and Souvenir de Monsieur Boll, which seem to be Roses of a sluggish circulation, so to speak, and equally liable to disfigurement by frost in winter and drought in summer. Of the darker Roses the worst injured were Duke of Albany and Duchess of Bedford, then Alfred Colomb and Marie Baumann, but it was a pleasant surprise to find that Horace Vernet had come through far better than had been anticipated.

Of the Roses that were not seriously injured, first and foremost comes Ulrich Brunner, whose long shoots, grown on various stocks and in several situations, showed no sign of damage from base to tip, so that this sterling variety in addition to being immensely vigorous and not liable to mildew, and also producing flowers of the first rank with great freedom both in summer and autumn, and retaining its foliage till the very last, appears, moreover, with yet another claim to be considered everybody's Rose, as being perfectly hardy. Violette Bouyer was almost as little hurt, the shoots only being discoloured a very short way back from the tips, and this may now fairly claim the title of the best and hardiest white Hybrid Perpetual. Another Rose that seems perfectly hardy and shows no trace of the effects of the winter is Her Majesty, which was

HENRI JACOTOT. Engraved for THE GARDEN from a photograph lent by his family.

that the variety was raised from seed of a Tea that had been fertilised by some Bourbon Rose. From recent correspondence with Mons. F. Jamin, it appears probable that one of the parents of Gloire de Dijon was the Bourbon Madame Desprez, but no one seems to have any very definite idea as to what the Tea scented parent may have been.

Be its origin what it may, however, Gloire de Dijon remains the delight of Rose growers in every part of the world where Roses can be grown, and its raiser, the late H. Jacotot, whose portrait is engraved in this week's issue of THE GARDEN, will be thought of by all grateful rosarians as having been a benefactor of his race. An ingenious writer in a foreign contemporary has lately been endeavouring to show that no Rose can be of real value, or a true credit to its raiser, unless both its parents are

may enjoy it all the year round, and if ever, for some heinous crime, I were miserably sentenced for the rest of my life to possess but a single Rose tree, I should desire to be supplied, on leaving the dock, with a strong plant of Gloire de Dijon.

*** Admiring often the beauty of Gloire de Dijon, both in cottage and other gardens, we thought last year that it would be well to find out something of the raiser and give a portrait of him if possible. We found on inquiry that no portrait had been engraved; we succeeded in getting a photograph, through the kind aid in the first instance of M. F. Jamin, of Bourgl-Reine, and afterwards of Mr. Webber, of the Botanic Gardens at Dijon, who kindly communicated with the family of Henri Jacotot. We have the pleasure, therefore, of offering the first portrait engraved of a man who has added a great charm to our gardens. Jacotot lived and was a nurseryman in the town of Dijon,

left fully exposed and entirely unprotected. It is to be hoped that the unfavourable reports that have come from America will not prevent people from giving this Rose a fair trial out of doors before assuming that the faults there alleged against it must of necessity characterise it over here. Because American growers find themselves unable to force Her Majesty satisfactorily, that is no reason why it should not be admirably adapted to out-of-door culture in this country. It certainly does not appear to force readily, but when allowed time to develop, its magnificent qualities of size, form, finish, and purity of colour may unquestionably be seen under glass to advantage, as witness the plants recently finely flowered at Cheshnut, which, moreover, showed no trace of mildew, whereas the variety is said to have been overwhelmed in America, although it should be noted that Mr. Peter Henderson expressly stated that he saw no trace of this pest on the 10,000 plants growing at Shepperton in 1885. Although, therefore, it is a matter of the first interest to rosarians in England to obtain the earliest possible information about the behaviour of any novelty in America, yet it should be borne in mind that the conditions of Rose growing are so essentially different in many important particulars in the two countries that it does not at all follow that the experience of good growers with particular varieties in the one will be identical with that of fellow-workers in the other. Dupuy Jamain is, of course, well known as a hardy Rose, and was practically uninjured, and among the red Roses E. Y. Teas was remarkable for the soundness of its wood throughout. All the Duke of Edinburgh family stood well, including also Duke of Teck, Reynolds Hole, and Sultan of Zanzibar. Gloire Lyonnaise, with the exception of a slight discolouration here and there in the two-year-old wood, was unharmed, and the comparatively recent Alphonse Soupert, as well as Catherine Soupert and the fine dark Jean Soupert (all three seedlings, by the way, of Lacharme's), escaped well enough. It was a great relief to find several favourite varieties, commonly regarded as delicate, such as Louis Van Houtte, Duke of Wellington, Xavier Olibo, and Mons. Nomman, appearing quite fresh and healthy. Prince Arthur seemed even less hurt than General Jacqueminot, and Charles Lefebvre, though cut above, was sound enough below, the same remark applying to Lord Bacon. Beauty of Waltham, J. S. Mill, Thomas Mills, Duke of Connaught (Paul's), Annie Laxton, Heinrich Schultheis, and Marguerite de St. Amand were all right enough, and Captain Christy was certainly the best of the Victor Verdier race, while, though Mdme. Gabriel Luizet's two-year-old wood was done for, the young shoots were safe. Last, but not least, A. K. Williams, in spite of the discolouration of the tops of the shoots, did not show the stain further than half, or at most two thirds of the way down the stem, and suffered far less than either Alfred Colomb or Marie Baumann. Of these three, A. K. Williams is now breaking far the most evenly and strongly, and need not, therefore, where the other two can be grown, be considered too delicate or tender for general cultivation.

In localities where Marie Baumann gets very much injured in winter, it may be worth while to make special note of the total immunity from harm of E. Y. Teas, whose flower, if not always quite so large, makes a very fair substitute for Marie Baumann in point of colour; and to those who are given to bewailing the tenderness of modern Hybrid Perpetuals it may fairly be pointed out that the only variety of which plants have been killed outright by a winter,

including temperatures so low as 7° Fahr., was Mdme. Prosper Laugier.

Among the Teas also one variety made itself conspicuous by its tenderness; for, of all the sorts grown, Madame Bravy was the only one of which plants were entirely destroyed by the frost. Of all the Teas on the walls, Madame Bravy was the most hurt; of all the established plants of Teas in the open, whether on Brier cutting or seedling, whether covered with Fern or left entirely unprotected, plants of Madame Bravy alone succumbed altogether. Belle Lyonnaise, however, made a very good second, being killed to the ground, as it was last year: probably, owing to the late season, the wood was not well ripened and so suffered unduly, but there is no doubt that the variety is a tender one, though the plants are breaking strongly in most instances from the base. Both Lamarque and Ophiré were a good deal disfigured, especially the former, but they have survived. Catherine Mernet, Niphotos, Amazone, and Souvenir d'un Ami appeared cut up to about the same extent, their shoots being discoloured to within an inch or two of the collar. Rubens and Perle des Jardins were rather better, and Marie Van Houtte better still, but a good deal harder hit than had been anticipated. Maréchal Niel on its own roots or on Brier was badly hurt, fully four-fifths of each plant having to be removed at pruning time. But, on the other hand, plants of this variety worked on Rosa polyantha were less injured than examples of any of the numerous other Teas and Noisettes amongst which they were growing. Out of twenty plants there were only six of whose shoots it was found necessary to remove more than a few inches, and all are now breaking evenly throughout their length; whereas those on Brier have as yet hardly moved. Rosa polyantha seems to make a stock well adapted to the needs of Maréchal Niel and the climbing Teas at least, as it is very vigorous, grows early, and is nevertheless perfectly hardy. Of other climbers, William Allen Richardson was but little hurt, and Cloth of Gold on a south wall suffered surprisingly little, though on the same aspect as that on which Maréchal Niel was much damaged.

Of the non-climbing Teas, Grace Darling did not suffer in the least, hardly a shoot being discoloured more than 6 inches from the tip, so that another feast of its charming rosy tinted flowers may again be confidently expected this year. Caroline Kuster was the next best, little but the two-year-old wood being stained of the plants on the walls, and not much more in the open. Anna Ollivier, Francisca Krüger, and Souvenir de Thérèse Levet all got well through; and a pleasant surprise was afforded by the discovery that the loveliest of all Teas, Comtesse de Nadaillac, had not sustained serious injury. This variety, though it only as a rule makes small wood, gets it thoroughly ripened, and so, perhaps, is in a better position to withstand a hard winter than sorts which are liable to make a larger, but pithy plant, like Madame Bravy. Souvenir d'Elise Vardon is another dwarf-growing Tea which may be said to have weathered the storm in a satisfactory manner, the ripened shoots appearing quite sound at the base. Hon. Edith Gifford is breaking throughout, as if determined to maintain its character as the most useful white Tea out of doors, and Jean Ducher, Madame Lambert, Innocente Pirola, Etoile de Lyon, and Jean Pernet are starting strong and well, and are each and all looking a great deal better than a good many Hybrid Perpetuals in their immediate neighbourhood.

Of the single Roses, the bewitching little berberidifolia Hardyi has survived on the open rockery, where, though it was only slightly protected with a few fronds of Bracken, it is now looking exceedingly well, and the buds inserted last summer upon seedling Brier stocks are growing strongly. R. sinica, though it does well on a wall, has been much cut back where tried in the open unprotected; but all the others are quite unharmed, and, as far as can be seen at present, the Rose hall will again this year be opened by Rosa polyantha, which in a few weeks' time, in the absence of any unforeseen catastrophe, will be wreathed, or rather sheeted, with snowy blossom.

Rosa maerantha.—It was remarked lately by "Hortus" (p. 225) that he had not come across R. maerantha in perfection away from a wall. This beautiful single-Rose, however, has passed uninjured through the recent hard winter, both growing as a bush and also trained on a pillar in the open entirely unprotected, and appears perfectly hardy. It is already covered with young growth, and a few warm days and nights only are required to render the terminal buds visible in their leafy wrap.—T. W. G.

Gloire de Dijon.—Amongst Roses which have stood the test of time, and which still not only maintain their position, but are ever increasing in popularity, few can equal Gloire de Dijon, for, although Maréchal Niel appeared a few years ago as if it would carry all before it, it must be acknowledged that, as an outdoor Rose, it is as much inferior to Gloire de Dijon as it is superior to the latter under glass. I have grown Gloire de Dijon in all sorts of forms and positions out-of-doors, and it is always satisfactory; and as a wall climber I do not think that any Rose excels it, either as regards beauty when in bloom or the length of time during which it continues to produce its lovely blossoms. It is one of the earliest and latest of Roses. Who has not seen glorious examples of this popular Rose on the sunny sides of villa and suburban residences, with its strong shoots of the preceding year's growth, perfect wreaths of delicately-coloured flowers? We have a plant of it here covering a large space of south-west wall that is seldom seen without blooms or buds on it. Under a continuance of mild weather, this grand old Rose well deserves the title of perpetual-flowering, and it is no slight boon to have a variety on which one may depend to furnish even a few blooms to cheer the dark days of early winter without the aid of glass. Therefore, to anyone about to plant wall climbers, whether on mansion, villa, or cottage, I would say, if you have only room for one, let it be that well-tried Rose Gloire de Dijon.—HANTS.

SHORT NOTES.—ROSES.

Pruning Marechal Niel Rose.—I have a Maréchal Niel Rose on its own roots planted outside and trained inside an old-fashioned vinery, now used as a greenhouse. It was planted nearly three years ago, and has grown so vigorously that the whole roof is almost covered with it. It is now flowering abundantly, but the lower part of the plant is inclined to make wood, and there is not room in the house for the branches to make more long shoots. Under these circumstances what would you advise? Would it be well to cut the branches back very close, perhaps even cut away part of the woody stem? I trouble you with this question because I understand that it is not considered advisable to prune Maréchal Niel Roses very severely, but in this case I hardly see what else can be done. I am anxious not to injure the plant through ignorance, as it is a remarkably fine one, and is loaded with buds and blossoms.—V. M., *Dorchester.*

Marechal Niel Rose failing.—We have a house of Maréchal Niel Roses planted out. It is a large cold house used for Chrysanthemums, &c., and the Roses are trained against wires running by the side of the walks. There are 30 side lights, only ventilators which we have recently had nailed up. In spite of every attention and care these Roses are one after the other cankering off. The shoots grow freely and healthily to 5 feet and 6 feet and then gradually die away, first of all looking yellow and sickly. Can you suggest any cause for this? They are planted in good loam, and watered occasionally with farmyard manure water. They are not all affected, as some are growing and flowering splendidly. What we would especially ask you is, what is likely to produce canker under

the circumstances, and would you advise growing this Rose in such a frame under such conditions as those stated?—MARSHALL BROS. & CO.

FLOWER GARDEN.

DURABILITY OF THE ROOTS OF THE JONQUIL.

GROWING out of the turf in the pinetum overlooked from my bedroom window is a small clump of this charming little favourite. It numbers perhaps a score of roots, one-half of which flower every year, when in due course the tops die or are mown down. At the present time it is the exact counterpart of what it was nearly thirty years ago, and, judging from the fact that this spot formed the entrance to an old kitchen garden, which was done away with in 1812, there exists but little doubt that this handful of roots have played their interesting part every year since the battle of Waterloo. How much longer they will last it is impossible to say, as they are neither helped nor hindered by plucking, manuring, or digging, but manage matters entirely in their own way. This year the flowers are unusually late, but they will be none the less welcome.

LENT LILIES, of which we have scores of acres, also are late, Easter having passed before many of the flowers were ready. A few years ago these, combined with wood Anemones and Primroses, formed one of the most beautiful sights it is possible to imagine, but a change, I am sorry to have to say, has come over the scene. The mad craze for wild flowers set in; people fetched them by carriage-loads; the poor folks followed suit. Agents set up in Leebury, offering so much a dozen for small bunches for the northern markets. Our woods suffered; the young coppicing was trampled underfoot by hordes of women and children and a few lazy men, who, finding a pheasant's nest, knew what to do with the eggs. The craze grew; people in distant towns could not exist without a continuous supply of Lent Lilies; free fights between woodmen and the pilferers took place, and we were put to the expense of employing the police as well as private watchmen. Had a few of the depredators, especially the long-coated section, been served with summonses, the traffic might have been checked, but this course was objectionable; consequently we have had a yearly battle, not with, but for, the flowers. People said, why all this fuss about a few wild flowers? Why prevent ladies and their children from leading their carriages with these, and later on with branches of the beautiful crimson and white Hawthorn unmercifully torn from the trees? Why prevent the masses from devastating the beautiful woods they are allowed to drive or walk through free gratis for nothing? Simply because liberal owners, after allowing visitors to gratify the senses of sight and smell, do not wish their woods and fences ruthlessly trampled under foot. Whilst granting all reasonable latitude to pickers of a few handfuls, they do not wish the bulbs bled to death by the drawing of every flower as it opens, and future crops nipped in the bud by literally trampling to death every bit of young foliage at the most critical stage of its existence. This is what has happened here, and the same thing no doubt is going on in other parts of the country. The damage to the bulbs themselves the first few years does not show itself, but in course of time there is a sensible diminution in vigour, flowers and foliage are weaker, decidedly later, and less plentiful. If anyone doubt this let him draw all the blooms out of his best Hyacinth bed, and beat the door mat every morning for a fortnight on the foliage; he may then leave his poor wounded and bleeding plants to themselves, and, if not before, certainly next year he will agree with me in saying that the owners of beautiful woodlands must not lose any more time if they wish to preserve our flowery dales in their enchanting beauty. When well-dressed Goths and ragged Vandals get thoroughly used to the privilege of rambling over beautiful parks, they seem to overlook the fact that they should assist in protecting Nature's richest gifts for the enjoyment of the owners as well as the multitude. Here, they do nothing of the kind, but having stripped the hillsides of the choicest Ferns, and

filled the churches and their houses with Lent Lilies, they think themselves badly used because they may not send the remainder to market. This coercion they resent by carving their initials on the backs of garden seats, by stripping a favourite *Acacia* of a world-famed piece of Mistletoe, and tearing this parasite from our druidical Oak. When Enville, Witley, and other noted places are closed, the masses may sing "Rule, Britannia!" but they have only themselves to blame for the withdrawal of privileges which they cannot appreciate.

W. COLEMAN.

SELECTIONS OF DAHLIAS.

WHEN a selection of say twenty-four varieties of what are known as show Dahlias is given, and no descriptions are appended, those who are unacquainted with the flowers find it very difficult to get any definite idea of the character of leading varieties. Even when descriptions are given they are often somewhat misleading, and so I have thought it might be serviceable if, at the outset of the Dahlia season, I were to give the Dahlia-loving readers of THE GARDEN a classification differing from what is usually given, and at the same time one that will enable them to select types to their liking. I will commence with twelve dark Dahlias, comprising flowers of one shade of colour, or flowers in which two dark shades, one deeper than the other, are found in combination. My list is as follows: Harry Keith, Thomas Hobbs, Imperial, James Cocker, James Vick, John Henshaw, Joseph Ashby, Joseph Green, Lord Chelmsford, Prince Bismarck, Prince of Denmark, and William Bawlings. It may be remarked and it will apply to all the lists I intend to give, that the flowers named are all approved exhibition varieties. The best twelve light Dahlias—white, blush, delicate lilac, buff, mauve, or pink—will be found in Emily Edwards, Georgiana, Herbert Turner, Hope, Mrs. Gladstone, Mrs. Harris, Mrs. Dadds, Prince Arthur, Vice-President, Seraph, Ethel Britton, and Mrs. Stancomb. The best yellow self Dahlias are *Aeone of Perfection*, Cecilia, John N. Keynes, Leab, Mrs. G. R. Gifford, Muriel, and Tolson (For). The best twelve tipped and edged will include the following six from the show class, viz.: Mrs. Langtry, Henry Walton, T. J. Saltmarsh, Lady Gladys Herbert, Miss Cannell, and Harriet Tetterell; also the following six, which are classed among the fancy flowers: Jessie McIntosh, Maid of Athens, Miss Annie Milson, Mrs. Saunders, Peacock, and Fanny Sturt. A further list of striped flowers will comprise all fancies, because all striped blooms come under this heading; they are General Gordon, Gaiety, Henry Eckford, Rev. J. B. M. Camm, George Barnes, Rebecca, Pelican, Professor Fawcett, Henry Glasscock, Adventure, and Charles Wyatt.

On the occasion of the coming grand National Dahlia Show at the Crystal Palace on September 2, some Veitch memorial prizes are offered for Dahlias to be shown by amateurs, and there are two classes—one for nine self-coloured show Dahlias, and another for nine parti-coloured flowers. Into the former class can come almost all the dark Dahlias named above, the yellow selfs, and such flowers among the light Dahlias as can be regarded as self-coloured. The parti-coloured flowers will include all that are tipped and edged and also striped. This is introducing quite a new feature into Dahlia exhibitions, and it will be interesting to see what the result will be. I am decidedly of opinion that the change will be found acceptable to Dahlia exhibitors. And there are open classes also for dark, light, tipped, and striped Dahlias, and the lists I have given supply the names of the varieties that can come into each of these classes. In the nurserymen's classes, the old and arbitrary distinction between show and fancy flowers is got rid of, and they will be shown together. This is an innovation that breaks down a merely artificial distinction, and that with positive advantage to Dahlia exhibiting generally.

R. D.

Primroses in sun or shade.—I think if "A. D." (p. 314) had seen our bed of Primroses lying flat on the ground through being frozen, and

afterwards thawed by a bright sun, which spoiled both the foliage and the flowers, he would have felt, as I did, that they would have been all the better if they had been in a position sheltered by some overhanging branches. I shall not expose them again to such violent changes of cold and heat, because if they had been under the shade of a tree they would have been protected from frost. I think with Mr. Douglas that these coloured Primroses do not differ in any way from the common ones in their requirements as regards soil and shelter. The most satisfactory lot I ever grew was in a shrubby border, shaded by overhanging trees, and where spring frost did not reach them. I quite agree with "A. D." that very little can be done in dividing these Primroses, and if anyone wants a stock of plants they cannot do better than raise them from seed, the present time being suitable for raising plants to flower next year. J. C. C.

Primula Allioni. This gem among the European mountain Primroses has been for some time past one of the loveliest of the rich collection of alpine plants in the York Nurseries. It is in growth one of the most diminutive of all Primroses, but the flowers are large, absurdly large compared with the leaves at the time of flowering. The blooms are as large as those of the common Primrose, but are stalkless and of a splendid rose-purple, which is in contrast with the pure white centre. It is one of the rarest and choicest of all alpine Primulas, and anyone who has an alpine garden and does not possess it loses a great beauty. Like most Primroses of the mountains, it is regardless of cold, and the cold weather at York of late has in no way narrowed the beauty of its flowers. W. G.

Primula marginata. This is a very beautiful species, and I would like to add to Mr. Wood's remarks in THE GARDEN (p. 394) that there are many varieties of it. We grow the varieties grandiflora and caerulea obtained from Messrs. Backhouse. I exhibited the last named form well in flower at South Kensington at the Primula exhibition. I have grown it in pots for nearly twenty years, and find that it flowers well when liberally treated. I have not grown it in a sunny position either; the plants are usually placed with other alpine species during the summer on the north side of a low wall. To see this species in all its pristine beauty one must visit the York nurseries of Messrs. Backhouse in April; it is a sight never to be forgotten—the large masses of it in flower in various positions in the rock garden. How has this species been produced is a question which might seem superfluous, as we read in "Alpine Flowers" "that it is a native of the Alps of Tauria and Daphny and various ranges of the south of Europe, but not of the Pyrenees." I can also testify from practical experience that the cultural directions given on p. 323 of "Alpine Flowers" are correct. I have raised several plants which are undoubtedly *P. marginata* from seeds of *P. villosa* var. *niva* of the *Botanical Magazine*, tab. 1161, the *P. nivalis* of gardens. Has anyone else raised seedlings from this plant? and if so, it would be interesting to know what variations they have had. The largest proportion are pure white *P. nivalis*. J. DOUGLAS.

Erythrina crista-galli. Many years ago this curious, but beautiful flower was considered a fit subject for flower garden or even conservatory decoration, and although it has lost none of those good qualities, the plant is now seldom met with in any garden. Some years ago I saw it growing well and flowering profusely in large beds in front of the conservatory on the lawn at Panshanger Park, near Hertford. Mr. Ruffett, the gardener, thought much of the plant. He treated it as a hardy plant, leaving it out of doors all the winter. The treatment necessary to grow it well is very simple; it thrives in a moderately rich, but well drained soil, pressed firmly about its roots. Beyond stirring it up occasionally the soil should not otherwise be disturbed. It is a plant of rather strong growth, and about the beginning of May throws up its shoots, which will continue to grow fast until August, when it flowers for two months or more. The flowers are scarlet and somewhat resemble a parrot's beak. They are produced in racemes, and these with the glossy foliage make it one of the most noble and attractive plants in

the garden for two or three months. When it has done flowering, its shoots should be allowed to remain until they turn yellow, thereby ensuring the thorough ripening of the buds at the crown of the plant; cut them off down to within an inch of the crown and cover with rotten manure during the winter months. It can be propagated in two ways, one from young shoots starting from the collar of the plant 2 in. or 3 in. long, or by making cuttings of the old flower-stems when quite ripe, plunged in bottom heat in a close frame.—T. RECORD.

PANSIES V. VIOLAS.

A SERIES of dry, hot summers seem to have told against Violas as bedding plants and Pansies for ordinary border purposes. In southern districts heat and drought are far more antagonistic than are wet and cold, for Pansies and Violas are far hardier than many give them credit for, especially ordinarily grown as hardy plants. Small seedlings or newly-rooted cuttings may perhaps suffer if planted out into open ground in October, because they cannot become established ere frost comes. If such plants cannot be put out by the end of August or early in September, they will be better off in frames or seed-beds until the spring, when they can go out early with assured safety. But older plants seem

to be harmed by winter. During the past two winters I have seen many thousands tested by the weather, but they have braved it well. These, however, although comprising fancy, English, and self-bedding kinds, with Violas also, having always been planted out during the previous summer, have been so well established in the ground as to be enabled to defy snow, frost, or rain, and even our wretched metropolitan fogs, the worst tests of all for plants to pass through. Of course Pansies, however hardy, are not unconscious of the average nature of the season, and move slowly and show bloom only sparsely yet; still, there will be a rich abundance of bloom presently, especially should the rain (which seems imminent) come, and with it really soft, spring-like weather. Most people have their fancies amongst hardy flowers, but whilst actual fanciers of the Pansy are not so numerous as its exceeding beauty deserves, yet it is liked by all. That is due to its hardiness, accommodating nature, easy increase, and not least, its large, showy flowers. There is some tinge of sentiment hanging over the Pansy, due perhaps to its old cognomen of Heartsease, but sentiment weighs little with modern gardeners, of whatsoever section they may be. We are now so terribly utilitarian, and grow Pansies less for sentiment and more because they cheaply give us beautiful flowers in exceeding abundance. In reference to the distinction between Violas and Pansies, it is now hard to draw the line; constant interbreeding and selection have brought the two sections so close together, that no link is wanting between even *Viola cornuta* and the finest and most perfect of Pansies, although individually divided by most marked differences. Pansies have become in numerous cases bedding Violas, and Violas have developed into Pansies, so fine and effective are the flowers. Still, we find no difficulty for our own purposes in defining a *Viola* as a dwarf-habited, spreading, and profuse-blooming plant, hardy, early, and rapidly increased by cuttings or division. Ordinary Violas have small flowers or of moderate size, which are regarded less for their form and substance, and more for their abundance and effectiveness. A few years since Violas were in great request as spring bedding plants. Either spring bedding is gone out of fashion, or else some other plants have considerably displaced Violas; and yet it must be admitted that it would be hard to find any class or family of plants which give so readily, so early, and so profusely more bloom, or make better bedders.

We have whites, yellows, blues, and purples in abundance, and some diverse or mixed colours have not been wanting. It is hard to see how in any good spring garden Violas can be dispensed with, and yet there seems to be just now a great lack of interest in them of a most unreasonable kind. Perhaps the fecundity which marked Violas a few years since brought satiety, but a few years of rest

may be productive of renewed interest, and if so it is hoped that it will not be strangled by the rapid introduction of indifferent novelties, so many of which, whilst pretty, lack the very requirements which make a good bedding variety. If we find Pansies holding on to popular favour longer as bedding plants, it is chiefly because these latter have larger flowers, and there is always existent in the masses a taste for size in flowers, even though quantity may be lacking. The special feature of any good bedding *Viola* is, that if its blooms be much smaller than those of Pansies, yet they are far more abundantly produced, so that the loss of a few flowers makes little difference in the mass. Large-flowered Pansies, however, cannot afford to lose a few blooms in that way; still, with so many persons mere size is the one essential. This criticism applies chiefly to Pansies used for bedding purposes, those employed for ordinary decoration or grown for the production of exhibition flowers being regarded from a different standpoint, as with these, in the estimation of growers, size, combined with quality and rich colouring, are the chief requirements. Of these the Belgian or fancy kinds give the finest results, and in variety of form and colouring may vie with any other flower grown. If anything should tend to make Pansies once again popular, it certainly will be found in the exceeding beauty, combined with size, found in the flowers of the fancy section. The old Pansy fanciers, of whom hardly one now exists in the south, found their favoured subjects in the English or belted and self-coloured kinds. There was not very much variety found in a dozen of white ground belted or yellow ground belted flowers, some nice distinctions, as with *Carnations*, *Picotees*, &c., being essential to create differences. The same may be said of the self hues, chiefly white, yellow, and purple, these showing trifling diversity in shade, form of flower, or size of blotch.

No doubt the old Pansy florists found points of beauty in their favoured flowers not so discernible to ordinary observers, but the range of the florist, nevertheless, was a limited one. Fancy Pansies, on the other hand, refuse to lend themselves to nice distinctions. To meet the regard of exhibitors they should have size, form, substance, and broad dense blotches; but these are features which the most unlearned in Pansy lore can admire, and rightly. Still, there is no room for refinings, and no end to variations in colouring. A big bed of fancy Pansies affords bewildering beauty, although not producing the same striking effect that a mass of some single-coloured *Viola* does. In this latter case the whole mass of colour is absorbed at a glance. In the former case, every flower demands special notice, because each one is a picture in itself, and a picture which very often puzzles artists faithfully to copy. Whilst fancy Pansies have robust habits, they perhaps are less compact-habited than are those of the English strain, but older plants which give more growth show this tendency to straggle less than young ones. How easily they are raised from seed may be seen in many gardens, and not least in those places which supply the market trade; but further, they are propagated by division readily if lifted and transplanted early in the autumn. To this end the blooming wood should be sacrificed early in August, the result being that new growth is encouraged from the roots and a tuft of shoots is formed. Some may be removed and placed in pans or boxes of sandy soil under hand-lights in the form of cuttings, most of which will in a few weeks make excellent plants. The old plants, carefully lifted and divided, each tuft giving several rooted pieces, should be dibbled out into a bed of good soil and, if needed, be kept well watered for a few days. In about a month these will have become well established, and thus may be transplanted into other quarters if desired for the winter. Strong plants put out in the autumn give the finest heads of bloom in the spring, whilst weaker ones, or those put out in the spring, bloom only after the heat of summer is being felt. Tens of thousands of plants, apart from seedlings, are reared in this way around London, as the demand for them begins the moment a bloom is expanded, and flowers can hardly be got out too early. The hawkers and others interested

in the sale of Pansies give the preference to the fancy kinds, because of their colours, whilst all very big flowers are in considerable request. A. D.

BEDDING OUT.

THOUGH frequently quoted as an advocate of carpet bedding, I can honestly assert that never once have I made a bedding arrangement that the word "carpet" would fitly describe; not once, I repeat, have I had an arrangement of plants with a perfectly even surface (which a carpet must have) or of intricate design, nor one composed entirely of tender plants, and it is now extremely unlikely that I ever shall, for experience has taught me a more excellent way than using even half the tender plants I used to do. But still bedding out is demanded of me, but, very fortunately, I am left to my own will as to how and what plants to use, the only conditions required being effectiveness, with sufficient coloured foliage plants and flowers as to make it worthy the name of a flower garden. I am but a poor hand at descriptive writing, so cannot enter into details, and it must therefore suffice to give a general outline of the rules I adhere to in respect to bedding arrangements. Before proceeding further I ought to say that the garden with which I have to do is an elevated plateau of geometrical design, but not of the severest type, there being no fancy figures nor statuary, but merely a few vases of simple design. Such a garden must, therefore, be planted in something approaching uniformity of design and colouring, so that one is precluded from exercising that liberty in regard to variety of plants that would otherwise be an advantage. Necessity, however, though sometimes a hard taskmaster, is a good teacher. Restricted space, restricted designs, restricted diversity of plants, and yet there must be the grandest and at the same time a lasting effect. Such was the discipline I had to undergo, but from which I emerged with a fair amount of credit, and now long usage has made the once tedious task a pleasure. But to revert back to the rules of procedure I follow in planting such a garden. They are—uniformity of plants, not necessarily the same kinds, but of uniform height and habit; next, hardiness—plants that will last a long season, and that will withstand wind and rain without being seriously injured; next, colour—the brightest that it is possible to use, having due regard to the neutral tints of trees and shrubs with which the colours should harmonise; next, a true balance of colour over the entire garden, no one colour to predominate; next, the freest possible use of all kinds of hardy shrubs that do not seem out of place in flower-beds or arranged in what I call "sentinel" positions on the greensward, such as at the angles of beds and ends of vistas of turf. By adherence to these rules I have for many years managed to plant our parterre after the bedding-out fashion to the satisfaction of those most nearly concerned and to the pleasure of very many besides. The work, from being a task, has thus grown into a pleasure, and it is not the less so because I have been able to discard a great number of tender plants that took up much valuable time to prepare, not to mention the house room they required, and which now is at liberty for growing plants for room and conservatory decoration. To this last-named phase of the subject must be credited the reform and improvement that have taken place in summer bedding out. The great work of propagation of plants and house room required proved to be the "last straws," and they have, indeed, broken the back of gorgeous colouring and fleeting effectiveness, and created a longing that is rapidly being satisfied for hardy flowers, of which, despite my supposed predilection for carpet bedding, I grow extensively and in great variety, and some few are even pressed into service for the bedded-out parterre, though at one time I could not tolerate the idea that any of them could ever be made to appropriately intermix with ordinary bedding plants, such as *Pelargoniums*, *Fuchsias*, and *Heliotropes*. I have, however, lived to alter my opinion, and now practise that which I once deemed an error by using the following perennials in bedding arrangements, namely, *Japanese Anemones*, *Rudbeckias*, *Delphiniums*, double and single-flowered *Pyrethrums*, *Spiraeas*, *Pentstemons*, *Antir-*

hinums, Pinks, and Carnations; and when to these have to be added summer-flowering and annual Chrysanthemums, Gladioli, Tigridias, Hyacinthus caudicatus, and a few others that I cannot just now call to memory, it will be seen that the list of bedding plants, apart from the orthodox section, is a large one; whilst as to hardy foliage plants, the list is still greater, if we admit the two sections of tall standard and dwarf carpeting plants. The latter consists of many varieties of the mossy section of Sedums and Saxifrages, Herniarias, prostrate growing Veroniceas, variegated Thymes and Golden Feather Pyrethrums, and the best of the tall section are several varieties of Japanese shrubs—Retinosporas particularly—Acers, Aralias, Bamboos, and Phormiums, all of which commingle most appropriately with tender subtropicals such as Cannas, Ricinos, Solanums, and Palms. Arrangements and mixtures of the various sections I hope to allude to another time.

W. WILDSMITH.

Wallflowers, single and double. These are now loading the air with fragrance. They are, like

months, but those that have braved it are bursting into flower. The old golden yellow variety with its long heavy spikes of bloom is opening freely now. It does best in a dry soil, and is very popular here by the seaside, as it attains a good old age, the soil being stony. The German double, with its mixed coloured spikes, after the style of Stocks, appears fairly hardy, but mixed colours do not seem so popular as the selfs, and they are certainly not so effective. They are mostly grown like Stocks by sowing early in boxes, so as to flower during the current year.—J. G. H.

THE MYRTLE-LEAVED ORANGE.

(CITRUS MYRTIFOLIUS.)

As a pot plant this is one of the neatest and best of the Citron tribe, of rather erect habit, and with its branches more closely clothed with foliage than in the case of the kinds more usually grown. The ripe and unripe fruits, of a deep orange colour, and rich, dark green with a highly polished and rather deeply grained sur-

Citrus myrtifolius. Engraved for THE GARDEN from a photograph.

all other flowers in the open air, very late this year, but none the less welcome or beautiful. Amongst single varieties Bedfont Yellow is very bright and clear. It has large smooth leaves quite distinct from other kinds, the flowers of a beautiful pale yellow, without a blotch or stain. Next comes the dwarf Blood-red, a general favourite and excellent for bedding, as it grows so close to the ground. We have them in full bloom and not 1 foot high. Great care is necessary to keep these sorts true. As they cross so readily, the bees are sure to hybridise them, and then one gets the cottage garden strain with the dark and yellow streaks combined which is the glory of the little garden plots at this time of year. I frequently stop and admire them when passing by the cottage gardens, and I find that they are spreading to the allotment gardens of our town artisans, who, having no gardens attached to their house, take the next best step to rent an allotment, and they plant flowers by the pathway for an edging. The double Wallflowers have had a severe trial during the last six

face, are carried in a bold, strong fashion, that gives a well-to-do air to a little tree such as the one engraved, and is a pleasant variety to the more weakly hanging habit of other Oranges.

Narcissus bicolor maximus and N. major superbus (Backhouse). Has any lover of bicolor Daffodils—the most beautiful section of all—suspected the existence of two varieties, distinct in character, yet running so closely that unless to a most practised eye they are identical? I am very anxious to settle this point, and will be glad to exchange flowers with the members of the Daffodil committee or traders who may grow stocks of bicolor. Mr. Brockbank, at Manchester, wrote on the subject in THE GARDEN some two or three years since, at the same time bringing into controversy the identity of the lost major superbus. If he will kindly send some flowers to me I will be much obliged; also, if he will send me a bloom of his majus superbus, as I fancy I recognised the flower in an English garden within the last month. The bicolor sections

are really fine here this year. Emperor is nearly 3 feet in height, a noble flower in the lorifolius class. I think that anceps is a distinct plant from rugilobus. The true anceps I have got from Scotland; the trumpet is longer and narrower, and the foliage also narrower. Rugilobus is in appearance a small Emperor. Anceps in shape is like Haworth's bicolor, but earlier.—W. B. H., Cork.

Border Auriculas. What a gain to our gardens in the spring would be clumps of C. J. Pery with its rich purplish hue, or of Hermione with its reddish maroon colour, as shown at South Kensington last week. But these fine self Auriculas only exhibit their gaudy tints in perfection when grown with exceeding care under glass, and even if they would thrive outdoors the blooms would present but a washed-out, miserable aspect. But, whilst we may not hope to obtain the rich hues of show Auriculas from these choice sorts in our borders, we may well hope to approach to them through careful sowing and selection from our sturdy and hardy border kinds. Auriculas are wonderfully pretty when grown under glass, because every feature of the flower is clearly produced. Outdoors, however, we do not want mixed colours or greatly diverse markings. To be effective as border flowers, self colours are most desirable, and dark hues specially are needed. We have a perfect wealth of yellow and white tints in spring flowers, but blues, reds, maroons, and crimsons are comparatively scarce. Polyanthuses give us dark tints in good variety, but whites and yellows are earliest. However, we want Auriculas as well as Polyanthuses; hence, we must strive for colours, the which shall make them effective. To do this, plants should be isolated and seeded separately, but the chief aim should be to secure rich dark self hues, the flowers being bold and carried on tall, stout, erect stems. Border Auriculas are wonderfully hardy and enduring. Slow of growth even from seed, they are slow to decay. Sow seed at once under glass for autumn planting and next year's blooming.—A. D.

Tufted Pansies. I was much interested in your plate of tufted Pansies in THE GARDEN. I have raised many seedlings from selected plants, and succeeded in obtaining a beautiful white variety and also a fine mauve-coloured sort; both of these never grew more than 4 inches high, and formed solid blocks of colour. I also aimed at getting sorts that would flower early in the spring, in which I was fairly successful, for if the winter was not too severe they would be in flower early in March in the west of England. With my own seedlings I also used freely the old Cliveden Yellow Pansy, which flowers at the same time and about the same height, and very pretty they were in lines or masses. The designation of tufted Pansy is a happy one for the style of growth the varieties you illustrate, as many of the so-called Violas are too loose in growth to be pleasing. The easiest way of increasing the stock of existing kinds is to cut them over early in August, and by the end of September they will be bristling with young growth, and in that condition they are admirably suited for planting where they are to flower in the spring, and such as are wanted to increase stock can be pulled to pieces and the young side growths dibbled into pans to be kept in cold pits or frames through the winter. If these pieces are planted out in the spring they will flower nearly all the summer. When required for massing in the spring, one-year-old plants are better than small pieces, and there is no better way of obtaining them than cutting back all the flowering shoots in August and planting them where they are to flower early in October.—J. C. C.

The Auricula rules.—I have long wondered why the alpine class of Auriculas should be so interesting and so poor in colour, but at the late show Mr. Douglas told me there was a rule that the margin must be shaded, which explains the matter. I always thought that having indulged their fancies to the full in requiring florists' flowers

to follow set forms, the alpine class was to lead to the presence of plants more like the natural form of the common Auricula; but it is not so. Therefore any tendency of the plants to turn, to show the naturally self-coloured characteristic of the Primulas, is stopped. It is a pity, because it is the pure self colours one sees upon the mountains where Primroses are so beautiful. What a pity the society will not permit changes which will allow of Auriculas being shown in a beautiful way!—R.

NOTES FROM BADEN-BADEN.

PRIMULA DENTICULATA ALBA, a snow-white variety, finished bloomingsome time ago, but an indigo-coloured variety of this Primrose is still in beauty. I have not yet been able to produce a really blue sport, but hope to do so if I live long enough. My work among Aubrietias is slowly progressing; the crimson Leichtlini is very conspicuous, but I am now working out a very different strain. *Anemone nemorosa grandiflora*, larger and better-shaped than the type, is a decided acquisition, and *A. fulgens Aldboroughensis*, raised by the Rev. J. G. Nelson, and for the possession of which I am indebted to Miss G. Jekyll, is also a first-rate plant. It is different from fulgens in its leafage, and the flowers are deeper in colour, very rich and full, and often nearly 4 inches across. A clump of *Muscari atlanticum*, with brilliant cobalt-blue flowers, contrasts well with the sombre slate-black spikes of *M. paradoxum*, and *Bellevalia leucophaea*, with sky-blue broad spikelets, is quite as showy as the rare true *Muscari Heldreichii*; this latter has the largest bells of the whole genus, and each of these is ornamented by a conspicuous white rim. *M. Szovitzianum* is of a pale cobalt colour, and its spikes are very large, sometimes 2½ inches. A new *Fritillaria*, from Cashmere, has showy orange blooms; it resembles *F. inodora*, but the colour is much better. *F. Schliemannii* has green flowers, yet they have a beauty of their own, and *Korolkowia Sewerzowii* discolor well deserves cultivation, and will be appreciated by all who admire less gaudy, though harmonious colours. *Iris orchoides* and its variety *splendens* in their shining yellow attire are also very desirable, being quite hardy. *I. prae-cox* and *pumila macrocarpa* are quite a mass of showy grey and blue. *I. Bludowi*, also of the dwarf bearded section, has large, shining, deep yellow flowers, which show off to advantage a neighbouring clump of the velvety violet-black-flowered *I. paradoxa*. *Podophyllum Emodi* strives hard to extend its beautifully marbled leaves to protect a number of its large flowers, which later on are succeeded by showy, scarlet, egg-shaped fruits. *Milla uniflora blanda* is a pure white sport, a gain of my garden. *Farsotia triquetra* is but a Crucifer, but a very showy one, bearing bright yellow flowers in compact heads. Among shrubs, *Pyrus Maulei superba*, a variety raised by me some years ago, is simply magnificent; its flowers are twice as large as the type and are deep blood-red, superseding in profusion of bloom all existent varieties of *japonica*. In a frame, some superb varieties of *Pyrus Tropeolum tricolorum* attract the attention of all visitors, especially one very long-spurred variety with orange-scarlet, emerald-green, and yellow flowers; these lovely climbers were frozen several times during this winter, and have not suffered in the least, and *T. edule* has even been tested, and found quite hardy.

MAX LEICHTLIN.

Baden-Baden.

SHORT NOTES.—FLOWER.

Magnolia Campbellei.—A handsome specimen of this, fully 18 feet high, is now in flower in the gardens of Mr. Crawford, Lakelands, Cork, and presents a magnificent appearance. Owing to the severe weather we have lately experienced, I did not expect to see it in flower.—W. H. B., Cork.

Delphinium Prince of Wales.—This variety is an excellent addition to the list given by "R. D." in THE GARDEN (p. 367). The flowers, thickly set upon the flower-spikes, which are freely produced, are light blue with an almost white eye. A strong, vigorous habit of growth renders this one of the best of the class.—E. M.

Trentalis europaea.—I have collected this plant for many years on the open moors of Perthshire, but had difficulty in establishing it at Oakwood till I made a bed of thin, poor peat near enough to our pond to give a little dampness. It

then grew freely and seeded itself. It is well worth taking a little trouble with for its own sake as well as for the pleasant memories it recalls.—GEORGE F. WILSON.

SOME USEFUL PLANTS FOR THE FLOWER GARDEN.

ALL who take an interest in the summer decoration of the flower garden must observe that Pelargoniums are not so commonly used as they were twenty years ago, yet there is plenty of room for a still greater decrease, as they are far outdistanced in beauty and interest by many of the hardy perennials. Some of the best of them are the following:—

SEDUM SPECTABILE.—This is a plant that is attractive alike in leaf and bloom. It is perfectly hardy, and about the month of July, when it will be 18 inches or 20 inches high, each stem will be terminated by a huge cluster of flowers of a warm purple or rose colour, and will remain in good condition for over two months. It is exceedingly effective as a mass or row in beds or borders, and is increased by division of the old roots. This should be done before the season is too far advanced.

PHLOXES. These are all useful in the highest degree, and although they are often seen planted in out-of-the-way corners, as if their owners were ashamed to see them, they form excellent flower garden subjects. A prominent mass of Phloxes here and there amongst the dwarfier plants is a relief, and I consider that they are not half so much used in flower gardens as they merit. I have grown a very fine collection, and although new varieties appear annually, they do not cease to be more massive in form and gorgeous in colour than their predecessors. I am delighted with them. As a rule we plant them and leave them, as I do not approve of annual transplanting and shifting them about from place to place. Plenty of manure when first planted and close attention to staking and tying while growing invariably produce satisfactory results.

TUBEROUS BEGONIAS. I hear from the superintendent of a London park as well as from a noted flower gardener in Scotland that these are the coming plants for flower garden decoration, and they are most excellent subjects, but it would be a pity if they ever became as common as Pelargoniums have been. Tuberosus Begonias might be grown in thousands of instances where they are still unknown before they would predominate, and no harm can result from advocating their culture in every garden, as they can be kept from year to year. This is greatly in their favour, and although they are somewhat late in the summer in becoming effective, yet they are exceedingly showy and very attractive during the autumn months. As they are generally regarded as greenhouse plants, some people may think that they would soon wither in the autumn, but this is not the case, as they are amongst the last plants in the flower garden to cease blooming. Bulbs are somewhat expensive to buy, but from a small packet of seed a good stock may soon be raised. Seed sown this season will produce bulbs that will make a fine display next year.

HERBACEOUS LOBELIAS.—Lobelias in the flower garden are almost wholly confined to those of the speciosa and pumila types, very pretty plants in their way, but not half so attractive as the herbaceous varieties, of which *L. cardinalis* and *L. fulgens* are the best sorts. They are quite hardy, and remain in the open ground all winter, like Phloxes. The first batch of them I ever received was from Mr. Coleman, of Eastnor Castle, and I shall always feel grateful to him for providing me with such a valuable subject for the flower garden. They attain a height of 2 feet and 3 feet, and produce spikes of rich scarlet flowers. We frequently mass them in the centre of large beds, and we have made short rows of them in ribbon borders, and in all cases they never failed to give satisfaction. Large plants may be divided at this season, and if planted in good soil will be effective by July or August.

SUMMER-FLOWERING CHRYSANTHEMUMS.—Many are apt to think that Chrysanthemums are best suited for an autumn or early winter display,

and that their charms of form and colour would be lost at a time when all kinds of choice flowers are plentiful, but the summer-flowering Chrysanthemums do not verify this, as although their flowers are smaller, yet they attract attention in the flower garden, and during September and October are very conspicuous. They flower very freely and continuously for weeks and months together. They are particularly hardy in growth and habit of blooming, as extremes of weather are less injurious to them than almost any plant I could name. Sunshine does not tarnish the blooms, and rain only makes them glow more brightly. They continue to bloom in late autumn when no flowers are visible on Pelargoniums, and they may justly be regarded as one of the most useful classes anyone can deal with. We never take any of our summer-flowering Chrysanthemums indoors or under glass, as they remain in the beds all winter, and when we wish to increase the stock we allow them to throw up a number of shoots at this time of the year, then the plant is wholly dug up, each of the young shoots is cut off with a few roots attached, and at once re-planted where it is to grow. They are very useful plants in the hands of those who have no glass houses or pits, as their successful culture may be carried on continually in the open air.

PYRETHRUMS.—It is only within recent years that these have become popular, as their huge double and single Daisy-like flowers charm all who see them, presenting as they do such a variety of soft and telling colours. It is no use to plant them singly, but an entire bed or beds of them will prove satisfactory in all gardens. They delight in a rich deep soil, and the flowers bear cutting admirably; indeed, it is a mistake to allow any old flowers to remain on the plants, as these impede the formation and development of fresh ones. They are easily raised from seed sown in the open at this time, and useful plants which may be used for immediate effect may be purchased at a cheap rate.

LANTANAS. These vie with Verbenas in the form of their flowers and gorgeous colours, and they do not possess that objectionable habit of dying off prematurely so often experienced in Verbenas. The flowers have a rather disagreeable smell, but this does not prevent them from making a grand display in the flower garden. They are not so hardy as the preceding plants, and must be reared under glass, but a few of them are a fine addition to the flower beds.

VERBENA VENOSA. This is by no means a new plant, but it is not so much or so often used as it ought to be. If raised from seed it will flower the same season, and the roots last many years. They may either be lifted in the autumn and stored in boxes during winter, or they may be left in the ground all the year round. It attains a height of 15 inches or 18 inches, branches very freely, and produces its little clusters of purple flowers in great profusion from June until November.

J. MUIR.

Narcissus Little Nell.—The severe criticism on this very distinct, though small Narcissus which was submitted to the committee on April 12 for registration is hardly fair. It is most desirable to avoid the indiscriminate naming of small forms of well-known varieties, and this was laid down as a general rule for the guidance of the committee, but in this instance the flower under consideration was acknowledged to be quite distinct from previously named varieties, and thus did not come under that rule. "D. W." cannot make out what it is an improvement on. Nor can I, for it is unlike any other in cultivation. He compares it with *N. pallidus prae-cox*, and suggests it may be a small form of that variety. Had "D. W." placed the blooms alongside those of *N. pallidus prae-cox*, he would have observed that in growth, form, size, and notably in colour they were distinct from it. Were we to give up growing varieties or species of Narcissus simply because they are small, we should forego some of the gems of this family, such as *triandrus*, *juncifolius*, *monophyllus*, *cyclamineus*, *minimus*, &c., which are most interesting to a florist and desirable for culture in pots, though of

little value as market plants or as ornaments in our gardens. As yet the stock of Little Nell is so limited that many who desire to possess it will have to wait some time before it can be procured.—J. T. Poë, *Riverston*.

DOUBLE PRIMROSES.

IN THE GARDEN of April 23 (p. 369) "A. D." says that he has not heard of any instance of a wood Primrose being found with even semi-double flowers. It may therefore interest him to know that I found a root of the common wild Primrose in a double (or semi-double) form, about four years ago, in Stone Wood, near Greenhithe, and removed it to my garden. Being then unfavourably situated for flower culture, it merely existed, bearing, however, a few flowers each spring, until I removed to my present residence last autumn, when I put it into a loamy border shaded by espaliers, and it now forms a handsome little clump, about 10 inches across, and has at the present time about fifty-one blossoms and opening buds. I enclose some of the flowers, and will be glad to learn whether they should properly be termed double or semi-double.

A neighbour of mine also tells me that, two or three years since, he had some double wild Primroses sent him, which were gathered in a wood near Cuxton, in our county. Referring back to your own columns, too, a correspondent in your issue of 22nd January last (p. 65) says that a double form of the wild Primrose has been found in a Cornish hedge-row, and I daresay many other instances have occurred.

With me this form blossoms somewhat later than the ordinary single Primrose.

In connection with this subject, I remember, as a youth, finding a *red* Primrose (single) in a Sussex hedge, far removed from any garden, but did not at the time give more than a passing thought to its singularity.

I am happy to say that with me neither Primroses, Violets, Wallflowers, nor Forget-me-nots—all of which grow in profusion among the Roses and bush fruits here—have been at all injured by the frost and snow this winter. Probably the bushes and fruit trees protected them. I expect that the frequent partial thawing and freezing again which occurred in most open places while the last snow lay on the ground caused the havoc of which "D. T. F." complains (p. 368).

Allow me most earnestly to second "W. G. M.'s" request for localities. Many interesting communications from your correspondents are practically valueless, as one cannot tell whether they are from north, south, east, or west, and so cannot know whether it is worth while to pursue similar methods or institute comparisons with one's own work.

North-ct, Kent.

RITMAN.

. The flowers sent are not really double in the proper sense of the word, but are what are generally known as semi-double forms. Ed.

Montbretias.—Since the appearance of *M. crocosmiaeflora* there have been several new varieties put into commerce; indeed, there is now a long list of names, but as the range in colour is not great it is difficult to find any marked difference existing between some of them. At the same time I flowered three varieties sent out last season by M. Lemoine, of Nancy, and found them all very desirable, and, what is more, quite distinct from *M. crocosmiaeflora*. The varieties were Bouquet Parfait, yellow centre, with the edges and tips of the petals orange-red; Gerbe d'Or, a plain rich golden yellow; and Etoile de Fen, bright orange-red, with small yellowish centre. Not only are these Montbretias very pretty when allowed to form clumps in the open ground, for here, in the suburbs of London, they are quite hardy if a little manure is spread over the crowns, but they can be easily grown in pots and flowered in that way. In any case they will need a liberal supply of water during the growing season, and should not be placed in a position fully exposed to the sun, otherwise the foliage is very apt to turn yellow and thus disfigure the

whole plant. *M. Pottsi*, which for many years stood out as the only representative of the genus in our gardens, is now almost ousted by the newer *M. crocosmiaeflora*, though I see this season *M. Lemoine* announces a form of *M. Pottsi* under the name of *grandiflora*, which he claims to be a very superior variety.—H. P.

Heildreich's Grape Hyacinth.—I notice in last week's GARDEN a reference to the Grape Hyacinth, blue and white. I send you three spikes of Heildreich's variety, which I think you will admit is far in advance of the ordinary variety.—M. SMITH, *Roselen, Prestwich*.

. The spikes are much larger in every way than the form botryoides. Another advantage is that it flowers later. Ed.

Primula Sieboldi.—In the show of *Primula* species at South Kensington last week sadly were the fine exhibits which Mr. Llewellyn has hitherto brought found wanting. Although that gentleman brought his plants from far Wales, yet he invariably brought plants, and not pieces; hence he always gave us in *Primula* species something to look at. Specially missing were the Penllergare clumps of *Primula Sieboldi*, with their luxuriant foliage and fine heads of elegant and various-coloured flowers: of the three dozen or so of *Primulas* shown not more than one or two were varieties of *Sieboldi*. In one case a huge *P. japonica*, with large leaves and a few poor flowers, made the most prominent feature, but small specimens, more interesting than striking, seemed the rule. Even the Kew collection, exceedingly interesting, no doubt, to botanists, contained barely one striking or effective plant, and certainly nothing so good as a fine bunch of any of the *Sieboldi* forms. Punny rock varieties, needing the aid of microscopes to discover their floral charms, hardly command respect from those accustomed to the size and gaiety of garden flowers. Perhaps the culture of *Primula Sieboldi* varieties has been neglected because the family is somewhat lacking in bright colours; and yet, with the exception of *P. rosea*, there are few species which give brighter hues. But in the matter of productiveness of bloom specially suitable for cutting if needed, no *Primulas* excel the *Sieboldi* section. Good clumps of from twelve to fifteen stout rhizomes, in 8-inch pots, form heads of bloom and leafage which no other hardy *Primula* suitable for pot culture can excel. It is very probable that crowding of crowns in the pots has been largely productive of barrenness—hence indifference. A. D.

PROPAGATING.

LAPAGERIAS. These beautiful greenhouse climbers cannot be struck from cuttings, or, at all events, if they are occasionally rooted in this way the occurrence is too rare to allow of this mode of propagation being generally followed. On this account they are usually increased by means of layers, and this operation can be carried out at almost any season, except when the plants are in full growth. Whether planted out or in pots the mode of procedure is the same, but as the *Lapageria* grows far more freely when the roots can run in an open border, the best shoots for layering are, as a rule, produced by those that are planted out. The branches can be layered either in an open border or in pots, the first method giving the least trouble, but if rooted in pots there is this advantage that they can be separated from the parent plant without disturbing their roots. For layering, good clean shoots of not too hard a texture should be chosen, and the portion to be covered with soil should be partly cut through about a couple of inches below a joint, the knife being then brought upwards till the joint is almost reached. The mutilated portion of the shoot must then be covered with soil to a depth of a couple of inches, sprinkling some sand around the joint at the same time. A long shoot may in this way be layered in half a dozen or more places, each held securely in position by a peg or two. As the *Lapageria* branches are very flexible, the shoots, if layered in pots, can be twisted round

in such a manner that the pots may be stood close together, and in this way can be better attended to than if scattered here and there. These layers must be allowed to remain undisturbed for a couple of years, and by that time, if reasonably successful, will have formed a base, from whence a shoot or shoots are pushed up, which will grow away and thus form the future plant. When these layers are lifted and potted, good fibrous peat with a liberal admixture of sand must be employed, and, after potting, the plants had better be kept close and shaded till root action recommences, which can be at once seen by the shoots commencing to grow. Some charcoal broken up to the size of horse beans and mixed with the soil will greatly assist the formation of roots, not only in the case of *Lapagerias*, but with most other plants. *Lapagerias* when once established will frequently ripen seed, and in this way great numbers of plants can be raised, but the progeny is very frequently inferior in flower to the parents, but, of course, there is, as is usual in the case of seedlings, a great difference amongst them. The pods should be gathered when ripe, and the seeds being extracted are better if sown without delay. For the purpose, well drained pots or pans may be used, the most suitable soil being sandy peat, sifted moderately fine, and pressed down firmly about an inch below the rim of the pot.

The seed being sown must be covered with about a quarter of an inch of soil and then watered, when a pane of glass may be laid over the top, and if plunged in a gentle bottom-heat germination quickly takes place. They will also come up as well, but slower in a greenhouse temperature. In any case a sharp look-out must be kept for slugs, as they are very partial to the young growing shoots, and a few aphides will injure the plants greatly in a day or two.

Attention need be now directed to *Conifer* seed that was sown early in the season in a slightly heated structure, which conditions are the best for raising the scarcer kinds, as if properly attended to the loss amongst them will be very small. The young plants are rather liable to damp off during their earlier stages, more especially if sown rather thickly, and as soon as any decay sets in the young plants should be pricked off. Soil of a loamy nature with an admixture of sand is very suitable for the purpose, and the young plants should have their naked stems buried at such a depth that the seed leaves are just clear of the surface of the soil. A free circulation of air should be maintained around the young plants, as by these means decay is to a great extent prevented, and they grow up stout and sturdy. When grown in frames the same rule will apply, viz., to maintain a constant circulation of air, and to prick off the young plants on the least signs of decay appearing. In the case of the larger kinds whose roots are too long to allow of their being dibbled in without injuring them, they may be potted into small pots, using the same soil as for the others. One great point to bear in mind is that the plants must not be left too long in pots, as they acquire a cramped character, which is likely to tell greatly against their success afterwards. To prevent this in planting the roots should be spread out in as far as possible a natural position, and the soil pressed firmly around.

EURYA LATIFOLIA VARIEGATA. This Camellia-like shrub, so much valued for its beautiful variegated foliage, is not an easy subject to propagate; indeed, failures are frequent, but it can be struck fairly well from cuttings, though this operation often takes considerable time. The cuttings should be taken about this time of the year, or a little later, according to the conditions under which they have been grown, and must consist of shoots of the current season's growth in a half-ripened condition. The weaker shoots strike root more readily than the very stout and succulent ones, and as, generally speaking, the entire growth of these is from 1 inch to 6 inches long, the whole shoot forms a very suitable cutting. It should be separated just at the point of union with the older wood without leaving a heel of the harder growth at the base. The bottom leaf or leaves being cut off, all is ready

for insertion. As it is very necessary to keep the cuttings close after putting them in, if there are no propagating cases at hand suitable for the purpose they may be covered with a bell-glass, and in that case the size of the pots employed will depend upon the glasses that are at hand, but where it is intended to put them in a close case, pots of 4 inches in diameter are very suitable for the purpose, as half-a-dozen cuttings can be very well put around the edge, and in this position they strike root more readily than elsewhere. A soil largely composed of sandy peat with a little loam sifted fine is very suitable for the purpose, and they must be well attended to in the matter of shading, as if they are allowed to flag the chances of success are small. On this account they should be put in as soon as possible after being separated from the parent plant.

COLLETIAS.—These peculiar spiny shrubs appear at first sight to be rather unlikely subjects to strike from cuttings, but such is not the case, for they root very well if pieces of the branches are put into pots of sandy soil and stood in a cold frame. The formidable *C. cruciata* is not at all difficult to root; indeed, of a number of cuttings put in last year nearly all have formed roots. T.

CHRYSANTHEMUMS.

E. MOLYNEUX.

I NEVER saw the plants improve so much as they have done during the last three weeks, owing possibly to the fact that, until recently, they were in a backward state, being weakly and having small leaves, and these not of a particularly good colour or texture. The long-continued severe wintry weather, when the plants had to be covered up more than was good for them, combined with an almost entire absence of sun for many days and biting cold east winds, all detrimental to the proper consolidating of the growth of such a succulent plant as the *Chrysanthemum* in its youthful stages of growth, have affected them very much. All *Chrysanthemum* plants ought now to stand upon a dry bottom of coarse ashes or cinders, where all superfluous moisture can quickly pass away, and ought to have ample space between each, so that a sturdy growth is maintained in all stages. This item is not nearly so much taken into consideration by many would-be growers as it ought to be, for it makes in a great measure all the difference between success and failure. It often happens that space is limited; hence the crowding together of the plants. My advice is then, under such circumstances, not to attempt to grow more plants than can conveniently be managed; far better to grow only half the number and attend to them properly. The plants are now assuming that gross character both in the stems and foliage which denotes vigorous health, and is a good foundation towards future success. Mildew often makes its appearance upon the leaves of the young plants, generally in damp, sunless weather, and this pest is much aggravated by a too confined atmosphere. The moment it makes its appearance dust the plants affected with flowers of sulphur; that of a brown hue is the best, for the reason that it is not so objectionable in appearance as the ordinary colour. Green fly is a troublesome pest which infests the points of the young plants, and if allowed to remain for ever so short a time quickly spoils the tender leaves, which disfigure the plants in time, and at the same time cripple that free growth which is so essential. Tobacco powder, applied by means of a distributor, is by far the best method of exterminating this pest, and within twenty-four hours syringe the parts affected; this leaves all clean and free from both powder and fly. After several successive warm, sunny days a gentle dewing over the leaves of the plants with the

syringe with tepid water about 3 p.m. will be beneficial towards promoting a healthy growth. Any spare plants not required for growing in pots may, after a time, be used to fill up gaps in either the shrubberies or at the backs of the herbaceous borders. Such plants should now be placed out of doors at the foot of a south wall, if possible, where they will become gradually hardened off preparatory to being finally transferred to their permanent quarters, which should be done about the second week in May.

DWARF PLANTS.—Where much furnishing has to be done in the autumn either indoors or in the conservatory, it often happens that suitable dwarf plants for the fronts of the stages or for filling jardinières or vases in the house are scarce; unfortunately, there is not an over-abundant supply of kinds adapted for the purpose named unless special means are taken to grow the plants properly and as circumstances require. Plants 1 foot to 1 foot 6 inches high are always welcome for this purpose. The best variety to achieve this object that I am acquainted with is *Seur Melanie*. It is naturally dwarf in habit and also retains its foliage in good condition for a long time. It is very floriferous, and, what is of great importance, all its blooms expand at the same time, thus making it very effective as a pot plant. At the end of April or early in May divide the old stools or plants of last year's growth and plant them out in good soil, allowing ample space between them. Failing these old plants, young ones of the current year's growth may be used; should the summer be very hot and dry give a thorough soaking of water to the roots occasionally. Secure the growth as it advances to stakes in any kind of a rough manner, and about the 20th of July take off the tops 5 inches long and insert them rather thickly in 4-inch or 6-inch pots, using sandy soil enriched with some Mushroom bed manure. Place the pots in a propagating case in a cool house in the same way as for cuttings early in the year. Shade them from the sun for a few days till roots are emitted, gradually harden them off, and remove them outside to a bed of ashes in the full sun. When they are growing freely supply them liberally with liquid manure, and when the bloom buds show colour allow all to remain; support the branches either by placing one stake in the centre and tying the shoots to it in the same way as *Mignonette* or *Bouvardias*, or place a neat stick to each plant; indeed, this is much the best way, as owing to the weakness of its peduncles the flowers of this variety have a tendency to droop. Another way of treating this excellent kind so that larger plants are available more resembles the bush method of growing other varieties, excepting that the cuttings are not inserted till a month later, thus rendering the plants smaller, and consequently more dwarf, which is the aim when cultivating these plants for the purpose named. Some cuttings should be struck in February and more in March, and by these means a succession of flowers can be maintained. As soon as rooted pot them singly into 3-inch pots, placing them in a frame close to the glass, keeping the frame close for a few days until new roots are made, and at the same time pinching out the points of the shoots. Keep the plants sturdy by free ventilation in favourable weather. Continue to top the shoots when from 3 inches to 4 inches long of those rooted in February until the middle of June. During the last week in that month transfer them into pots 6 inches or 7 inches in diameter, and by this time the shoots will have broken from their last topping. Those rooted in March should be topped when from 3 inches to 4 inches long, continuing the operation till the first week in July, and when

they have broken into growth again transfer them into their flowering pots, using the same sized pots as for the earlier struck ones.

Another method of producing useful little plants in small pots is as follows: At the end of June peg a few shoots down to the ground from the plants put out in the open for supplying tops for the system previously described in *THE GARDEN* (p. 402). When roots are formed pinch out their points, and when the first break occurs after this topping cut them off and pot singly, placing them in a cold frame for a few days till new roots are formed. If small plants of the incurved kinds are wished for, the *Rundle* family, such as *George Glenny*, pale primrose, *Mrs. Dixon*, orange-yellow, are the best kinds. Young plants are placed out of doors, as in the case of *Seur Melanie*, and frequently pinched until the middle of June. About the first week in August take off the points of the branches about 6 inches long, placing six or seven in a 5-inch pot, treating them in a similar way to the others, with this exception, that the buds should be reduced to one on a shoot; these will then produce neat, little incurved flowers on plants about 1 foot high. In the Japanese section, *Dr. Macary*, lilac, is a variety well suited for this treatment, as it has stout, deep green foliage, and is of a stiff habit of growth requiring no support for plants of the height named. *Peter the Great*, pale lemon, is another sort well suited to this style of cultivation, its habit of growth being erect and of a stiff character.

GARDEN FLORA.

PLATE 595.

NEW HARDY PASSION-FLOWER.

(*PASSIFLORA CÆRULEA* CONSTANCE ELLIOTT. *)

AN addition to the list of climbing plants suitable for open-air culture in this country is such an uncommon occurrence, that peculiar interest attaches to the appearance of a new white-flowered variety of such a popular old favourite as the hardy blue *Passion-flower*, which, in favourable localities for its growth, is one of the most beautiful wall-climbers in cultivation. When this white-flowered variety, *Constance Elliott*, was first announced, many were induced to think that an albino of *Passiflora cærulea* belonged to that large family of mythical plants that exist only in the imagination of nurserymen, and certainly the first flowers that were seen of it did not go far to refute the idea, as they were decidedly too green to be termed white. Since, however, the plant has become widely distributed and grown under various conditions it has quite answered to the description given of it at the outset. Its flowers, as our plate shows, are not snow-white, but ivory-white, both in the sepals and the fringe, which in the original blue *Passion-flower* is of a bluish shade. The *Constance Elliott* variety, moreover, is a vigorous grower and exceptionally floriferous, much more so, in fact, than its parent, but why such is the case is unexplainable. In every place where the common *Passion-flower* succeeds, this new white variety will no doubt supplant it, on account of its being more attractive in flower, and a more delightful garniture for a verandah, alcove, pergola, or wall could not be chosen from the long list of open-air climbers. I have seen the *Constance Elliott* *Passion-flower* several times growing and flowering in the greatest luxuriance, but I have never been more struck with its elegance and beauty

* Drawn for *THE GARDEN* in the Hale Farm Nursery by H. G. Moon, July 10, 1886, and printed by G. Sovereyns.

than when I saw it festooning a verandah, last September, in M. Herbst's garden at Richmond. It was getting dusk at the time, and the flowers seemed to stand out in bold relief from deep green foliage in a charming way, and I at once saw what a valuable open-air climber it was.

The variety, I believe, originated in a Devonshire garden, and was distributed by Messrs. Lucombe and Pince, of the Exeter Nurseries, and few among the many beautiful plants sent out by that firm surpass this one in value. It has now become tolerably common, for as soon as it was known to be "a good thing" no further recommendation was needed.

The original *Passiflora cerulea*, represented in the annexed woodcut, is one of our oldest garden plants, having been in cultivation since 1699. It is a native of Brazil and Peru, in the mountainous districts where the climate

and white, becomes rosy in autumn, and the plant when covered with flowers and fruit is really splendid. — E. FORGOTT BY ONE.

*. The plant received is variegated with blotches of white, but is not sufficiently developed for us to pass an opinion as to its merits. We will grow it and report later on. — Ed.

FRUIT GARDEN.

W. COLEMAN.

ORNAMENTAL APPLES.

It is more than gratifying to find all classes of readers and planters constantly inquiring for the best Apples for special purposes. The first and foremost consideration no doubt is profit, and quite right too, as there exists but little doubt that our Apple culture has a grand future before it. Many difficulties no doubt have to be overcome. Legislators and landowners have their parts to perform; practical gardeners and

fruit in the autumn. But these do not answer our purpose; we want free, hardy, handsome growing varieties for planting on the home estate and in the pleasure ground. These in the first few years of their life must have protection from hares, rabbits, and cattle. Once established, they must be hardy enough to take care of themselves in one sense, and they must be good enough to be worth looking after when they arrive at years of maturity. We want varieties whose pure white or bright crimson flowers render them especially handsome in the spring, whose rich golden or crimson fruit repeat the picture in the autumn; and last, but not least, we want and must have sorts that will stand against all comers for culinary or dessert purposes in their respective seasons. The hedgerow system of planting ornamental or timber trees is bad; therefore sites in the open park, the Grass field, or in the grounds of sloping banks where the soil is good, naturally drained, and shelter from cutting winds can be secured; moreover, if possible, they should be arranged in groups above the line of fog and spring frosts. Many strong-growing trees hold their own and do well when introduced near the margins of young plantations. Weaker growers form charming groups when thrown out well in front of masses of Conifers. Dot planting as much as possible should be avoided, and instead of mixing the sorts each group should consist of one variety, as they will then blend and throw each other up, not only when in flower, but also when the fruit is ripening. If the work is to be really well done, I see no reason why the ground for these groups should not be trenched and, the better to save future labour, sown or planted with some dwarf kinds of Evergreens. I say this advisedly, having some years ago planted the beautiful *Pyrus spectabilis* and the old Norfolk Beaufin on deeply trenched loam, previously sown with the common Gorse and white Broom. Here the first is a sheet of crimson flowers, and this excellent Apple which I am now sending to market produces good crops whenever orchards are not a total failure. Next, as to

VARIETIES, which should not be too numerous, I would take the cream of the sorts that do well in the neighbourhood, and as these within the next six weeks will be in full bloom, planters with an eye to effect, with catalogue in hand, may mark down a few whose habit and bloom suit them best. If strong trees that will attain the dimensions of forest trees are wanted, I would go in heavily for that grand late Apple *Hambledon Deux Ans*, *Blenheim Orange*, *Northern Greening*, *Flower of Kent*, *Beauty of Kent*, *Tower of Glannis*, and the improved *Bess-pool*. Other groups might be formed of *Alexander*, *Lord Suffield*, *Lane's Prince Albert*, *Norfolk*, *Hereford*, and *Striped Beaufins*. The latter do not make large trees, but they are marvels of fertility, and the fruit hangs very late in the autumn. Some might choose the *Kentish Goff*, a telling tree in the spring, but being of second quality I should not plant it. In warm, sheltered situations I should give preference to *Claygate Pearmain*, *Worcester Pearmain*, with its pure white flowers and crimson fruit; *Irish Peach*, the *Old* and *New Hawthorn-dens*, and *Cox's Orange Pippin*.

Many more might be selected, but here we have sufficient for a start, and, provided readers of THE GARDEN wish it, I will extend the list before planting time comes round in the autumn. One delicious Apple for very select spots within sight of home I have omitted, and that is the old *Ribston-flavoured Margil*. Half-a-dozen

Passiflora cerulea.

is mild, about the same climate, in fact, as the southern part of these islands, where the plant is thoroughly at home, and not only flowers profusely, but ripens its fruits. There are few prettier sights in autumn than a wall clad with *Passion-flowers*, and hung in profusion with their great egg-shaped fruits of orange-yellow amidst the luxuriant green foliage. Like all climbers of a similar degree of hardiness, the blue *Passion-flower* thrives best against a warm southerly exposed wall, though on other aspects it flowers well, and may even be grown on open bushes in some favoured parts, but under such conditions it rarely fruits well. In very severe winters, such as that we experienced in 1879-80, the *Passion-flower* is killed, unless protected; but the plant is so rapid in growth, that if a large plant is killed it may be replaced in a season or two if the young plant is treated liberally. There is nothing to say with respect to its culture, as it grows well in any good garden soil, the better if light and rich.

There is no other *Passion-flower* that can be grown successfully in the open air in this country, the majority of the species being natives of tropical and subtropical regions.

W. G.

Phytolacca albo-variegata.—We send to-day a small specimen of our new *Phytolacca albo-variegata*, which we hope will be a good addition to plants for grouping on lawns in summer. The foliage, which is now only green

fruit growers have theirs. All, in fact, who know anything about Apple culture or fruit markets should lend a hand, not only in the diffusion of knowledge as cultivators, but also in sweeping away the abominable tolls and vested interests which tell so heavily on the consumer as well as the producer. Further, they must educate the masses in large towns into the true belief that English Apples, although possibly less showy, as an article of food are equal to the finest in the world. We have repeated inquiries for the best selections of Apples for private use, for market, and especially for late use, and now within the past year or two there has gone forth a cry for ornamental Apples. Strictly speaking, all Apples are ornamental; all have their special use; the common *Crab* even, or the wilding in the hedgerow, are beautiful; indeed, from an artist's point of view it is questionable if many of our choice Apples can beat them when in flower in May or carrying their bright crimson

trees on the free stock would make a choice group.

PEACHES OUT OF DOORS.

MUCH has been written lately about the success and failure of outdoor Peach crops. Many failures might be traced to neglect of some of the details or methods of cultivation practised; one of these—a very important one—is the disbudding of the trees. In some cases it is not done sufficiently, thereby allowing the growths to become so much crowded that proper development of neither leaves nor branches can take place. Disbudding of the shoots which are not required for the proper development of the tree should be commenced directly the leaves are visible. By these means more time is allowed to take off what shoots can be dispensed with, at various times, so that a check is not given to the tree by allowing all to remain until a growth of several inches has been made and then removing all at once. To preserve an evenly balanced tree much depends upon disbudding properly. In the case of young trees the operation should commence at the top of each; this checks somewhat the flow of sap into the stronger parts and assists the lower and consequently weaker parts. All shoots intended for permanent use should be retained on the upper side of the branches.

FORM OF TRAINING.—This to a careful cultivator is an important item, as a well-trained tree will produce as much good fruit as one slovenly trained. As growth progresses the shoots should be laid in either by nailing or tying to wires as fast as is required. Some persons allow the branches to make a foot of growth before they think of fixing them to the wall. When they are laid in as soon as long enough to handle they receive in a far greater degree the benefit of the sun's rays on the wall. The growth as it progresses is solidified, and consequently is much better ripened in the autumn, a point absolutely essential to ensure success in the season following. The leaves of one shoot should not overlap those of its neighbour. As soon as the crop is gathered, whatever pruning the trees are likely to require in the winter ought to be done at this time, as by so doing, the remaining branches which are depended upon to produce the next season's crop of fruit have a much better opportunity to become thoroughly ripened. This has been our practice, and has resulted satisfactorily. We do not only remove some of the shoots of the current year's growth, but any weak or worn-out older branches are cut away where desirable to make room for others of more promising appearance, as it is upon the healthy young branches that the best crops of fruit are procured. We pay strict attention to preserving the foliage in a clean, healthy condition during the summer months. This, I consider, one of the most important matters. It is difficult to lay down a stated time when the trees should be syringed, as much depends upon the weather and earliness or lateness of the seasons, but as a guide, it is safe to begin when the fruit is taking its first swelling and when the nights are warm. From four to five o'clock in the afternoon we thoroughly wash the foliage of the trees with the garden engine, using tepid water; if the weather be very hot and dry the syringing is done every night, but if wet and cold it is varied according to circumstances. After a very hot day it is surprising what an amount of water the bricks will absorb. By these means the wall is made cool, which prevents in a large degree the spread of red spider upon the foliage, and this, coupled with the thorough washings we give to the trees, prevents spider from obtaining a footing at all. I find that gentle dewings upon the upper side of the leaves is not of much service, as it is on the under part of the leaves where the enemy lurks. I consider a tree infested with red spider while the fruit is making its second swelling in a very bad state, and not calculated to ripen the fruit thoroughly, or to lay upon a good foundation for the succeeding year's crop, because the preservation of healthy foliage is the only way in which to ensure success. We do not syringe the trees in the morning, because the night dews, coupled with the syringing the previous

evening, are generally sufficient to maintain a moist atmosphere about the foliage. Seldom it is that we are troubled with green or black fly since we made a practice of thoroughly washing the walls during the winter with soapsuds from the laundry. If the former should appear we use tobacco powder dusted on the points of the affected shoots, and to destroy the latter we use strong tobacco water, placing the liquid in a saucer and dipping the points of the shoots overhead in it. Some of our trees, particularly those upon an east wall, suffer a good deal in the early spring from blistering of the leaves, owing to their being exposed to keen east winds, which are prevalent in this part of the country. The only remedy for this is to pick off the affected parts as fast as they appear, and with warmer weather the trees outgrow this evil. As our trees are planted high we water very freely during active growth, and after the fruit is gathered we give copious supplies; a lack of water at the roots at any season if the trees are in good health is very detrimental to them. Often non-success with the trees outside may be traced to neglect in this one detail, especially when we consider what a quantity of moisture a brick wall will absorb. Whatever moisture is absorbed by the wall below the ground line is taken from the roots of the tree.

If the trees are well supplied with surface roots, we give occasional heavy soakings with liquid manure after the fruit has completed its stoning process. The quantity of water, both clear and liquid manure, to be given to each tree depends entirely upon local circumstances, such as the size of the trees, number of roots, whether they are deep or shallow, whether the soil is heavy or light in character; if the former, much less will be required. I have not mentioned what is perhaps the most important point of all to be observed, namely, the roots, because without these in proper condition success cannot be obtained. It often happens that when new walls are built, new borders made, and fresh trees planted, the soil round about and under the trees settles down considerably; while the borders, which are generally devoted to a crop of some sort or another, by the addition of annual manurings, soon get much higher than the tree-line; consequently, unless extra care be observed, the roots are buried to a great extent. To obviate this they should be lifted entirely. The best time is in September or early in October, bringing the roots close to the surface, covering them sparingly with soil; over this place a layer of fresh manure from the stables if the land is at all inclined to be of a heavy nature, but where the soil is more of a sandy character a mixture of cow and horse manure will be an advantage. Our trees always have a covering of one of these manures over their roots, laid on thinly twice a year at least. As the manure rots down the roots seem to revel in it. After the crop of fruit is gathered, if the trees do not require lifting, the roots are examined, and if at all bare a thin covering of loam is added with which has been mixed some old mortar. This is firmly trodden down and the mulching of manure applied, then follows a good soaking of clean water.

A firm soil for Peaches and Nectarines is essential to success. Keeping the roots in a proper manner by lifting them to the surface prevents the formation of those gross growths which are useless as fruit-bearers. Of course, all these details of culture which I have endeavoured to point out, were they carried out, would be futile in their object if means were not taken to protect the trees when in blossom. Many are the schemes adopted, such as placing fishing-nets and evergreen branches over the trees, but the most effective plan of protection is properly-constructed roller-blinds. These, with care, last a long time if they are made with what is called No. 3 serim canvas. Where rollers cannot be fixed, owing to low walls or other circumstances, a strong wire fastened under the wall-coping will support the blinds upon rings; these can be pushed to one end in the morning and drawn along again in the evening.

No doubt there are localities where Peaches will not flourish outside owing to atmospheric or soil influences; but the fact of their not succeeding in

many places is not owing to the fault of locality, but in a great measure to cultural details. A selection of early sorts is all in favour of out-door Peach culture; but I may say that I had last year a capital crop, which ripened well, of Walburton Late Admirable, and if this late variety will do well here (South Hunts) other early kinds will do in other districts not so favourably situated.—S.

It is years since Peach trees on open walls presented such a promising look as at present. They are not only wreathed with bloom, but, what is more important, the leaves are unfolding bright and clean, for it is just in the first flush of growth that they usually get crippled with fly, and once the leaves get curled and blistered, it takes half the season before they start kindly into growth. From where I am now writing a young tree is growing that has been admired by everyone that has seen it for its large showy blossoms, one side of the tree being in full bloom, while the other side was only in bud, and now the leaves on the one side and fruit thickly set are more forward than other trees in unheated glass houses. The reason of this is that a flue from a neighbour's house keeps the wall constantly warm, and although I never expect to see heated walls come into general use, I can testify in this instance to the Peach tree being evidently benefited by it, as we had very severe frost while it was in bloom, and although no covering was applied, I should say that 90 per cent. of the bloom is set. This tree affords yet another instance of the wonderful recuperative power of young trees. During three years it was a miserable-looking specimen with hardly a vestige of leaf left on it, but I persevered with giving frequent washings of soapsuds, and it grew away so vigorously that it is now as handsome a tree as anyone might wish for. It is surprising what wood a Peach will make in one season, and although Peaches on open walls were certainly deteriorating a few years back, I observe a decided improvement in them in gardens generally during the last year or two. J. G. Hunts.

NOTES ON VINES.

WISHING to renew the plants in our Muscat house with as little loss of time as possible, I decided to do half of the house at a time. The Vines have been planted twenty years in an outside border and brought through the wall into the inside border, in which they soon made roots. When I decided to renew them I cut off the stem just outside the wall and destroyed the roots, and made a new outside border, leaving the inside stem and roots untouched. This was done by way of an experiment, as I was uncertain whether or not there were enough roots inside the house to sustain the growth or mature the crop. I had not long to wait for the result, as they broke as strong as at any previous time, and showed more bunches than were wanted to furnish a crop. I allowed them to remain, and the fruit ripened as well as ever I knew it, thus showing that the loss of half of the roots had no effect on the crop. The Vines are equally as promising this season. When the old rods have finished off this year's crop they will be destroyed, as the young ones, planted last June in the outside border, will be strong enough to bear a few bunches of Grapes next year. The inside border can then be re-made, so that the actual loss of fruit during the renewal of the Vines is reduced to the lowest minimum.

Another Vine, which had been trained in a horizontal direction up one end of the house and down the other, and had a set of roots at each end, two years ago I cut in two, leaving about 1 foot of bearing rod on the end furthest from the old roots. This is growing and bearing as good a crop as the other, in which the sap flows in a natural direction. These two cases show that the Vine is an accommodating plant; but there is certainly a limit to its endurance, of which I have evidence in the case of a pot Vine that I had the curiosity to attempt to grow in peat Moss alone without any soil. The Vine was potted three years ago when dormant in a pot 14 inches in diameter in Moss, mixed with about half a pound of Clay's fertiliser. The subsequent treatment was the same as that given to other Vines. I did not expect to see it show fruit

(the first year, and to encourage it to make good wood I applied a small quantity of the fertiliser during the growing season. Each season it made satisfactory growth, but has never showed any fruit, thus proving that the Vine requires something more substantial than decayed Moss and concentrated manure to ensure its fruitfulness. J. C. C.

AMERICAN CRANBERRIES AND OTHER FRUITS.

I READ in THE GARDEN, Jan. 22 (p. 66) that the American Cranberry, "when cooked, is said to be very palatable." This statement sounds odd to us in America, where the Cranberry has come to be one of the staple fruit products. It is not only picked from the native swamps in many parts of the country, but it is also grown on a large scale. The leading Cranberry-growing States are Massachusetts (at Cape Cod and vicinity), New Jersey, Wisconsin, and Connecticut. Michigan, which leads in most fruit industries at the north, is also growing Cranberries to a considerable extent.

In New Jersey alone there are some 5200 acres under Cranberry culture. The entire crop in the United States last year from cultivated vines was probably not far from 600,000 bushels.

From these figures you will understand that the Cranberry is a very popular fruit in America. Especially will you appreciate this when you take into consideration the fact that thousands of acres of wild Cranberry marsh are annually picked over and the products sold or used for home consumption. Of course, we never eat the Cranberry raw. Its principal use is for sauces and pies. Its aromatic, rich acid is refreshing and wholesome. A considerable portion of the crop is now exported to England.

It is surprising how independent we Americans are in this matter of fruit. Nature has dealt liberally with us. It is only thirty years ago that the Cranberry was known only in a wild state; now it is much improved, and several good varieties have been produced and are now in cultivation. Fifty years ago our wild Strawberry was scarcely known to cultivation; now every valuable variety of our gardens is a product of our wild species, *Fragaria virginiana* and its var. *illinoensis*. It is only the amateur who now grows *Juncunda* and *Triomphe de Gand*, of European origin. Along our northern borders the European *Fragaria vesca* grows wild, but it attracts no attention from the horticulturist. All our Grapes of out-door culture—and that is the almost universal culture in this country—are products of our wild species. A few varieties, as the Rogers hybrids, are crosses between our own species and the European. Only three of our wild varieties have yet been ameliorated to any extent; while nine or ten more species are waiting to be taken in hand by the cultivator. Two species of Raspberry, the black and the red (*Rubus occidentalis* and *R. strigosus*), wild in all our woods, have given us the numerous varieties of our gardens and markets. The European sorts are grown only by amateurs. Our Blackberries and Dewberries, fruits of bright promise, are offspring of the *Rubus villosus* of all our coasts. Our best Gooseberries are also of American origin. Of course, these Gooseberries are by no means equal to the great, luscious fruits of your English gardens, but they are the only ones which can be profitably grown here. At the present time our native Plums are receiving much attention, and already a score of varieties are in the market. Twenty distinct wild species of *Prunus* are found in the United States.

Nor is this all. Many more species await the cultivator than have already responded to his care. America, of all countries, is the place where even the most studious can see the wonderful influences of cultivation and selection upon wild products. The originals of our garden plants still linger in our fields, and the progress of development has been so rapid, that men who are still active remember when the garden offspring did not exist. C. M. Hovey, who gave us the first good Strawberry, still lives and works.

I read with amazement the statement of De Candolle, in his "Origin of Cultivated Plants," that "the United States, in spite of their vast territory, which will soon support hundreds of millions of inhabitants, only yields, as nutritious plants worth cultivating, the Jerusalem Artichoke and the Gourds!" L. H. BAILEY, JR.

Michigan Agricultural College.

GRAPES MRS. PEARSON AND GOLDEN QUEEN.

MY experience in regard to Grape Mrs. Pearson is fully confirmatory of that recorded in THE GARDEN (p. 363) by Mr. Coleman. We have never kept it beyond the month of March—never attempted in fact—but on many occasions we have had it in first-class condition throughout that month. The high character given it by Mr. Coleman as well as by Mr. Barron in his book on Vines, more particularly in regard to quality, is hardly high enough, for whilst the flavour is more piquant than the Muscat, the rich, aromatic taste is as pronounced as is that quality in Chasselas Musque, and in these respects there is no difference between the Vines growing on the parent stock and grafted on the stock of Buckland Sweetwater, in both of which forms it is grown here. It crops prodigiously on both stocks, but, curiously enough, the Vine grafted on Buckland Sweetwater bears the more freely of the two, yet this variety (Buckland) has always proved a shy fruiter here. The only other difference that a foreign stock seems to have made is in the form of the bunch, the natural contour of which is more after the form of Chasselas Musque, namely, long, with added shoulders; on the Buckland stock the bunches run larger, the shoulders generally being of a size disproportionate too large for the length of the bunch. I have sometimes fancied that the colour was brighter on this stock, but several have said they could not discern it, and it may have been that "the wish was father to the thought," as at least, we have never been able to colour it beyond a pale yellow. Now for a word of commendation of a more unpopular variety, namely, Golden Queen. We bought both this and Mrs. Pearson from the raiser, the late Mr. Pearson, as soon as they were sent out, some ten or twelve years ago, and have grown them ever since, sufficient proof surely that they have turned out satisfactorily. As regards Golden Queen, the mistake the raiser made was to send it out as an early variety, as it is a Grape that takes quite as long to ripen as does Alicante, and is explicable only on the supposition that he had not thoroughly tested it. However, this was done, and it has no doubt tended somewhat to bring the variety into disrepute, because being planted in early houses growers found that at the time their Hamburgh, Foster's Seedling, and Buckland Sweetwater were ripe this Grape was still green and as sour as a Gooseberry; no wonder, therefore, that hard words were spoken concerning it, and summary judgment pronounced in the form of its exclusion from many vineries almost before the plants had got into full bearing. In this instance, however, impulse did not gain the mastery, and the variety was kept, and being grafted on Buckland Sweetwater stocks in an intermediate house it has now become an established favourite, the quality being so totally different to that of any other kind of Grape, for whilst the flesh is firm, crackling, and full of juice, the flavour is sweet with a faint smack of the Muscat in it. On the Buckland stock the colour is always a clear golden, and the berries longer than are those from the parent stock. There is no appreciable difference in the size or form of bunch, but the colour of fruit from Vines growing on their own roots is less bright, and sometimes from bad management in ventilation it is quite a dingy brown. The variety will not keep quite so long as Mrs. Pearson, but it has the desirable property of being just as sprightly and refreshing to the palate when shrivelled as it is when in a plump condition. W. WILDSMITH.

Strawberry plants in spring.—The following sorts of Strawberry plants planted on a border

facing east have stood the winter well, not a plant being dead or apparently in the least injured: King of the Earlies, The Captain, Loxford Hall Seedling, Goldfinder, Countess, Bletton Pine, Helena Gloode, Anguste Desaisne, Eleanor, Elton Pine, Frogmore Pine, President, Sir Joseph Paxton, and Comtesse Hericant de Thury. I cannot report so favourably on one lot of British Queen, for the plants at present appear to be injured past recovery. I may mention that when I was making up a selection of Strawberries two years ago, I received plants from various sources, and amongst them two different lots of British Queen, one from Kent and the other from the west of England. The Kent plants are the ones which are suffering from the effects of the severe winter, and seeing that both lots came from well-known sources, it appears to me that there are two different sorts sent out under the same name, and if so, it will account for the British Queen thriving in one place and failing in another. As the plants did not bear much fruit last season, having been planted late, I had no opportunity of comparing them, as I hope to do this year. Lucas is another sort which has suffered a good deal, only about a half of the plants being alive.—J. C. C.

SEASONABLE WORK AMONG FRUITS.

ORCHARD HOUSES.

ALTHOUGH the season is very late, forcing gardeners have little cause for complaint, as I find houses started on certain dates are decidedly in advance of the stage they had reached on this 1st day of May last year. Orchard houses are no exception to the rule, and, provided May flowers can grow without the assistance of April showers, of which we have had but one, and that was a heavy snowstorm, pot Peaches and other fruits will be well up to the mark, and probably more plentiful than usual. Until within the past few years the orchard house was looked upon as an expensive luxury, but now we find it doing duty for the early Peach house which is retarded for a month or more, and where the most suitable early varieties are selected for forcing, the result is a considerable gain in point of time, whatever may be thought of the quality. To those who must, and will, have ripe Peaches early in May, Ansden's June, Alexander, Early Louise, and other semi-clingstones answer very well, but fair quality ever being the test of merit, trees from a better section should be selected. Hale's Early is highly praised, I suppose because it forces and colours well; certainly not for its quality, as fruit from the most favoured spot under glass or against a wall can never compare with the A. B. C., the Mignonnes, Early Silver, and others with Noblesse blood in their veins. Although I have never tried the experiment, it has often occurred to me that a most interesting early houseful of trees might be made by potting up a given number of all the Mignonnes, including the new large Early, the Early Grosse and the old G. Mignonne, Royal Kensington, a very fine old member of the family, and Belle Beauce, not only the brightest Peach grown, but the parent of the large Early Mignonne, the cream of the cream of Rivers' best seedlings. All of these are of the highest quality, very handsome, and travel well when gathered and packed before they are quite ripe. I have often stated that shortening back the shoots of the past year may be deferred until the fruit is swelling. These remarks apply specially to the Mignonnes, which sometimes cast their intermediate wood-buds when kept too dry at the root through the winter. Once a good lead, with plenty of fruit behind it, has been secured, the summer pinching must have regular attention, otherwise there will be a rush of sap into a few shoots near the tops of the trees, whilst those near the rims of the pots as well as the fruit will suffer. When early houses have been thinned for the last time and the fruit shows signs of colouring, a little more heat with plenty of air may be given, as trees in pots placed in a warm medium will stand sharp forcing; but it must be borne in mind that the quality will be good in proportion to the length of time and the amount of sun and fresh air to which the fruit is exposed. Good mulching or top-dressing and feeding must, of course, be freely plied, and vigorous

syringing twice a day until the Peaches show signs of transparency, may be continued. When this stage is reached, a dry, warm atmosphere will favour ripening, and bring out the delicious aroma by which good fruit can always be distinguished.

Gathering the fruit.—When to the practised eye the most forward trees have reached the changing point the syringe must be withheld and the heavy root waterings reduced, but not discontinued, otherwise all the fruit will be ripened off in a few days. This slight check will soon cause some of the fruit on each tree to soften at the apex, but being hard near the stalk a few hours longer will do no harm. Still, every Peach should be gathered before it is dead ripe, as this process can always be completed in the warm fruit room, where they can remain until wanted for use. In this half-ripe state, however, the most delicate handling is necessary, as every finger mark leaves a bruise, and a bruise means premature decay; therefore, the better to avoid this, with a pad of cotton wool in the left hand and a pair of Grape scissors in the right, each Peach should be dexterously detached and placed on a square of silver paper in a well-padded, flat-bottomed basket. If daily gatherings are made and the Peaches are never handled, they will keep for a long time in good condition, and there will be no loss of fruit or flavour, as so often happens when people persist in allowing their Peaches to hang until they are dead ripe, the point at which fermentation and decay set in. Slightly under-ripe is the proper gathering state for home use, but when the Peaches are intended for travelling or market purposes they must be gathered as soon as they are full size, well coloured, and inclining to transparency. Each fruit should then be folded in a piece of silver paper and firmly packed one layer deep in dry, elastic Moss placed in shallow boxes. Being so tender many people approach the packing table under the impression that this operation must be tenderly performed, but this is a very great mistake, as tender fruits of all kinds should be made firm in the boxes, otherwise the packing gives way, when the finest samples are ruined by friction.

General houses.—The fruit in these, even without the aid of fire-heat, will now be set and swelling freely; indeed, many of the most advanced trees will have been disbudded and partially thinned. The management of a mixed orchard house from this time forward may be divided into a few simple operations, but simple as they are, they must be performed at the right time; they must be performed well, and the person in charge must be well up in details. Fire heat more or less may be given where time is an object, otherwise solar heat with early closing in fairly good summers will bring the finest fruit to maturity. Air, good food, and plenty of water are imperative. If we go back to the early days, we find the pioneer, Rivers, advising his readers to syringe well soon after six o'clock in the morning. To open the ventilators so soon as the temperature commenced rising, more air, as a matter of course, being given until the maximum was reached. Reduction step by step in due course took place when finally the afternoon bath with plenty of solar heat made all safe for the day. Our orchard houses have been greatly improved in appearance, but for all practical purposes the original is as good as the ornate, as we then as now had an abundance of light, and ventilation, if anything, has been rather cribbed by the modern builder; consequently, for hardy trees that must have room to expand and breathe plenty of fresh air, our progress from a cultural point has possibly gone a step backward. The most impatient fruits are Plums and Cherries. Pears were considered so, but once established in pots and well ripened they are quite as manageable as Peaches, and should occupy a good section in the mixed orchard house. So far, although morning frosts have been sharp, they have been dry; consequently the coldest, the most dilapidated houses are safe, and will continue so, provided we give insects the quietus on their first arrival; feed freely with top-dressing and liquid from the time the fruit commences swelling, and syringe the trees twice daily on fine days, especially during the continuance of this dry, harsh weather.

MELONS.

Under the false impression that Melons are swamp plants, many people make provision for giving them any amount of water and stagnant vapour, but they do not always lay good plans for producing the dry roasting surface so antagonistic to canker and essential to flavour when the fruit is ripening. The pot system offers many facilities for drenching, flooding, and feeding when the plants are growing and the fruit is swelling, and provided the stems are elevated up to or a little above the level of the rims of the pots, the change from moist to dry heat can be graduated to a nicety. In very early houses this state will now be necessary, and when the fruit shows signs of changing colour the supply of water poured in round the insides of the pots must be neither more nor less than sufficient to prevent the foliage from flagging. The afternoon closing with the atmosphere in a state of saturation must also be discontinued; but not so the heat, as a high temperature with a circulation of dry air is the main factor in securing flavour. If all the fruits on a given plant commence ripening together water may be entirely withheld, especially if any of the roots have found their way through the apertures into the sods of turf below, and cutting must be deferred until the aroma is strong, and the stalks, by cracking freely, show that their work is nearly finished. Sound Melons will keep for a long time after they are cut—some varieties longer than others, always provided they are kept in a warm room, from which fresh air is not excluded. It is, however, possible to keep them in a sound condition until their fine piquant flavour has passed away; therefore, growers should make themselves thoroughly acquainted with their capabilities before they try long keeping, as one good Melon is worth a dozen bad ones.

Where the pot system is regularly followed up there should always be a reserve or manufacturing pit for producing stock, one of the main points being quick growth from the seed to the finish. Immediately after the removal of the fruit from the first set of plants the pit should be thoroughly cleansed to free it from filth and insects, and the better to secure a sharp fermentation a portion of the old may be taken out and replaced with fresh plunging material. Leaves cannot be surpassed, as they give heat and vapour at the outset and food at the finish. When the bottom-heat ranges from 80° to 90°, strong plants established in their fruiting pots may be drawn from the nursing pit. Plunged to the rims at once, and provided all goes well, they will reach the flowering stage in a few days.

Succession plants now swelling off heavy crops of fruit will take copious supplies of diluted liquid at a temperature of 80° to 85°, according to the strength of the bottom heat. Ventilation should be liberal through the early part of the day, and shutting up with good syringing in time to raise the temperature to 90° must follow on fine afternoons. Melons under high pressure after the beginning of May swell very fast; consequently their feeding-time is short; but by top-dressing with rich turfy loam, very fine bone-dust, and other highly concentrated stimulants, fruit of the largest size consistent with quality can be secured. It is, of course, possible to over-swell Melons, as we sometimes see them coarse and as hollow as Pumpkins, but they are never good. Moderate feeding, therefore, is best, and the better to enable the plants to assimilate their food, all laterals should be judiciously pinched and trained over vacant parts of the trellis, as quality and flavour so greatly depend upon a profusion of clean, healthy leaves.

Melons in frames. If it be true that fortune attends those who know how to wait, those who have not yet turned out their plants are sure to be right, as May is undoubtedly the best month for commencing their growth in pits and frames. The hills for frame plants should be high, narrow, and solid; the plants not deeply buried should be placed on the very apex, as they should neither be earthed up nor open to flooding with water. Necessarily they need not be less than 2 feet from the glass, as short stems can be raised to the trellis, which, by the way, should be made to settle with the bed,

otherwise there will be danger of strangling. We do not hear much about the strangling or drawing of the stems of Melons to the cracking tension, but it is very common and the unsuspected cause of canker and collapse where large fruit and leaves cannot obtain supplies of moisture fast enough. Once fairly started, these frame plants, carefully guarded from checks, will make rapid progress and soon fill the space allotted to them. Quantity of vine is not, however, all we want; we must have quality, and this—a short-jointed, wiry growth—can only be secured by training thinly in a brisk temperature that will admit of liberal ventilation. If all the plants start well together, the pinching of the main shoots will induce a flush of female flowers, from which the crop of fruit should be secured, and these should be carefully fertilised from day to day, each shoot being drawn up to the influence of the sun, as moisture is an impediment. Modern growers sometimes pinch these shoots close to the fruit before they open, but the old school, no doubt including the veteran grower, the late Mr. Bailey, allowed their fruit to set first, and then pinched back to the first joint in advance. Whichever plan is adopted, the secret of success consists in thinning back to a given number of fruits of uniform size and age, that will be likely to run well together. Frame Melons should be very carefully watered until they attain the size of hen's eggs, when flooding with good liquid will help them; and the old-fashioned overhead watering with clear water at a temperature of 85°, about 3 p.m. once or twice a week, may precede shutting up on the hottest afternoons. On other days the syringe may be plied right freely, but the lights must be shut at once, otherwise scalding will follow. External management will include the linings, which must be renovated back and front alternately, and covering with good, dry mats, canvas, or other materials, throughout the season.

HOUSE CUCUMBERS,

either in pots or beds over hot-water pipes, will now take enormous quantities of water, and the roots will well repay liberal top-dressing. If their removal is anticipated, a good covering of rotten manure may be applied, otherwise it must be avoided, as strong, moist heat and manure soon fill the beds with worms. The syringe, too, must be vigorously plied, not only from within, but on fine evenings from without, as filth, spider, and millew soon take a firm hold on the stoutest foliage. Clear sulphur or soot water, and occasionally a solution of sulphide of potassium, may be used with great advantage, always provided the plants are thoroughly syringed with clear water and shaded the following morning. Next to cleanliness, light cropping must be constantly observed, as it is of no use trying to renovate beds, or resuscitate old plants, where they are heavily handicapped by a quantity of useless fruit. A good Cucumber-grower cuts off every unpromising fruit as soon as it shows, and by this means husband the vigour of his plants; he also ventilates freely on fine mild forenoons, and closes early with a strong heat and abundance of moisture. Treated in this way, systematic shading can always be avoided, especially where the trellises are movable, and can be lowered in summer to admit of a continuous circulation of air between the foliage and the glass.

Spring-sown plants, still clean and healthy, will now be giving plenty of fine fruit at the cost of very little trouble. The great rock to be avoided is overcropping; in all other respects treatment that will keep old plants in health will produce the most satisfactory results amongst young ones.

Frame plants.—These will now be very useful, as they will keep many families supplied during the time the winter house, heated with hot water, is producing its quota of Melons. The great secret in the culture of these, as of frame Melons, is quick growth, with plenty of side and bottom-heat, ventilation, the reverse of coddling, and early closing, with the overhead shower-bath. The best compost, as I have so often stated, is a sound fibry loam that will grow a good Pelargonium without the aid of rotten manure, old lime rubble, or rough charred garden refuse. When these are thoroughly incor-

porated and added as required, fruit of the finest quality and flavour may be depended upon. Frame Cucumbers should now be manipulated three times a week, otherwise a great deal of vigour will be lost, and independently of checks from the removal of arms full of vines, where points only should be taken, the plants will soon become infested by insects, when frame plants may as well be consigned to the limbo already prepared by "W." for frame Potatoes and cap-glass Cauliflowers.

Yet another very useful section of the family I must draw attention to, and that is the batches of plants intended for following these frame Cucumbers and other unprofitably forced vegetables. Good, hardy black or white-spined varieties are best adapted for this purpose, and they should be once pinched to induce side shoots, and well hardened to fit them for future treatment, which may be considered intermediate between the heated frame and the cap-glassed ridge. W. C.

FIG GROWING AND KITCHEN GARDENING.

THE reference made to my "jeremiad" on the prospects of kitchen gardening by Mr. Coleman last week shows that he, at least, did not appreciate my observations, which he says he had read, but which he could not have read carefully, or he would have seen that I still advocated the home culture of those crops that could not be had as good or good enough from the market, and among these I would include Figs, because they cannot be bought in this country, for I do not class fresh Figs from the tree and dried Figs "from Smyrna" together, as Mr. Coleman does. I know Figs can be grown out of doors, too, not only in his favoured county, but 500 miles farther north, and between these points. As to Mr. Coleman's remark that "surely the more a man grows of all kinds of fruit and vegetables the better his services will be appreciated," I would not endorse it. With those who take a pride in growing crops regardless of expense, outsiders have nothing to do, and it was not for them so much that I wrote. The only comment I would offer on such persons is that no credit attaches to their feats. Speaking generally, however, I say that crops that do not pay the cost of production do not represent useful services or energy, but only waste and extravagance, and are not commendable from any point of view. This, at all events, seems to be the universal opinion of those engaged in other productive industries, and perhaps Mr. Coleman will tell us why gardening should be an exception? When I see "able men having the charge of large gardens" growing poor, flavourless early Peas, for example, that never do anything like pay the cost of stakes and staking, let alone other culture, and when as many Peas as will supply the need and of better quality can be had cheaper in the market, I put him down as a man who is not doing much good in his generation. Late Marrows might be better grown at home. I fancy it would battle Mr. Coleman or anyone in a similar position to account for the use of a large portion of their kitchen garden produce. What becomes of all the acres of Cabbages, greens, Brussels Sprouts, Broccoli, Cauliflowers, Savoys, &c., to name only one class of vegetables? When we find in a moderate-sized kitchen garden perhaps 1000 or 2000 Broccoli grown, a proportionate quantity of summer Cauliflowers, and thousands of others of the Brassica tribe, and only a few people to consume such things at the rate of a spoonful or two each per day, and many days during the absence of the family when perhaps none are used at all, one wonders where it all goes. Can Mr. Coleman tell us? I think I can guess. Quantities go to seed or to waste in various ways unless sold, and there is as a rule no market for such stuff in season. On the other hand, where such things are bought at the market, even at a good price, it is surprising how few serve the purpose and yet leave enough for everybody without any waste. Supposing these things to be true to any extent, what good gardener can defend them? The truth is, the conditions of private gardening are greatly altered, and we shall be obliged to conform

to them, and those who realise the fact soonest will be regarded as the best men. W.

KITCHEN GARDEN.

W. WILDSMITH.

CAPSICUMS AND CHILLIES.

IF these are required in quantity for pickling in a green state, there is no more economical method than growing them in the open air. I do not mean by this that they must simply be planted in any position and in the manner common to most vegetable crops, for, though probably they would do well treated in this way in the most southern parts of our island, they will not do so here. Although favoured with a good climate and a light, warm soil, we have to assist these by giving over to them the warmest sunny aspect and a slight hotbed to start the plants into growth. Given these two conditions, we have never yet encountered the least difficulty in getting abundant supplies, ripe and unripe, from the open air. Our usual place for growing them is a raised border facing due south, and the heat to ensure a good start into growth is obtained by digging out a trench from 15 inches to 18 inches deep, and of such width and length as the plants are expected to require; the trench is then filled with the short Grass from the lawn, intermixed with any spare stable litter we may have; the soil dug out from the trench is then levelled over the bed, the bulk of fermenting material being limited; it is seldom that the heat ever reaches too high a figure, but planting should always be deferred till there is a certainty that it will not do so. A bottom heat of 80° is the highest at which planting may be done with safety, and when this temperature is not likely to be exceeded, planting out should be done as soon as the bed is made. The distance apart of plants will, of course, vary according to the varieties to be planted. For large-fruited and strong-growing varieties, such as Long Red, Long Yellow, Bell, and the handsome yellow-fruited kind, Prince of Wales, 20 inches or 24 inches is none too much; whilst 18 inches is ample for all kinds of small-fruited Chillies.

TIME TO SOW.—As with everything else, success is to a large extent dependent on a good start, and therefore good plants are indispensable; hence it is necessary that the seeds be sown and raised in heat early in March, that they may be ready for planting out by the middle of May. We sow thinly in pans, and place in a hotbed to germinate, pot off as soon as they can be handled, and grow them on in light, airy positions in early and second early Peach houses. Greenfly is sometimes very troublesome in the early stages of growth, and the most effectual way to destroy the same is to dip the plants in tobacco-water, a precaution that we always take immediately prior to planting out of doors, then syringing and heavy rain keep them free of insects. In the way of general cultivation there is really very little to be done other than keeping the plants well supplied with water, the bed clear of weeds, and the surface soil loose, that sunshine and air may the more readily exercise their beneficial influences. The more robust varieties require staking; in fact, it is safest to put sticks to all, and thus prevent breakage from high winds and heavy rains.

POT PLANTS.—We always grow a few in this way for house decoration, and on more than one occasion the plants so grown have been so poor in comparison with the open-air plants, that we have had a few of the best of them potted up

and that have done so well that the others were discarded, a proof of the superiority of open-air over indoor cultivation. On another occasion, late in the season, when an unexpected call was made on us for a quantity of ripe fruit, a manure frame was prepared, and a number of the best fruited plants transferred thereto, where they ripened off their fruit in an incredibly short time, due, I think, to the check of lifting, which arrested growth and promoted rapid maturity. Hence it will be seen that the open-air method of growth possesses other advantages besides the production of large quantities of fruit for pickling.

TOMATO CULTIVATION.

To those who have the requisite convenience, and require a regular and prolonged supply of Tomatoes, I would recommend them to grow them on the extension system. Its principal merits consist in producing a much larger quantity of fruit for a lengthened period with a deal less trouble than on the restrictive plan. The only drawback to its general adoption that I know of is that it cannot be so well practised outdoors on account of our seasons being too short, but in any moderately heated structure, with space for root action and a command of ordinary soil mixed with well rotted manure, the plan will be found very advantageous. It is, no doubt, well known that the Tomato will grow up the roof of a house or on a back wall with the vigour of a Grape Vine, and when once established will throw out a number of side shoots and fruit at every joint. These, if properly thinned and stopped at a joint or two beyond, will become ripe in regular order, and that, too, after the fruit on the main stem has come to perfection. After the plants have reached their allotted space in height they will become bare at the bottom, but they invariably throw up shoots from the base equally as fruitful as the others. The best of these should be selected and trained up in a regular way with a view to fill up all vacant space which will eventually arise, so that in time the main stem will have perfected its crop and can be cut away to make room for those to follow on. The Tomato is very liable to produce an abundance of shoots as well as a great quantity of foliage, but the former should be judiciously thinned and stopped, leaving only sufficient to maintain the vigour and health of the plants, as well as assist in the swelling of the fruit. This operation should be performed when the bulk of the fruit is set. The Tomato at this time will require liberal supplies of water and manure water twice a week. In my case I am compelled to syringe the plants twice or three times a day, as I have a span-roofed house with Vines on one side and Tomatoes on the other, and dwarf Beans underneath, an arrangement I should not recommend for general adoption, as the Beans are pretty certain to leave the houses well stocked with red spider. I wish it to be understood that I do not despise the restrictive system of growing Tomatoes, because it has its merits, and recommend it to those who have a limited space, and who require fruit in a shorter time and perhaps of finer quality.—THOMAS RECORD, *Folkington Manor*.

—I read in one of the calendars the other week that in training Tomatoes we are to take care to "pinch the shoots" beyond each truss of flowers, in order to encourage fertility. It is astonishing how gardeners stick to this hereditary practice of starving and pinching everything into fruit. This pinching of the Tomato is simply suicidal, and impairs the plant's fertility by one half at least. Yet you see the system in practice constantly—purely rule-of-thumb. An answer to the question, "How does a Tomato grow?" will show the absurdity of pinching. The plant naturally grows in a free, branching manner, and produces a truss of flowers at or near the end of every shoot. These flowers will set, and the shoot pushes beyond if not meddled with, produces another truss of flowers which sets also, goes on growing, and flowering, and fruiting again, and so on till the end of the season if the fruit are gathered as fast as they ripen, and the

plant is well fed at the roots, the plant carrying fruit in all stages of progress to the last produced flowers. If any pruning is wanted, it consists in removing altogether such shoots as room cannot be found for, but a shoot should never be pinched or shortened. It will be apparent from this description of the plant's habit that the pinching beyond the fruit, so often recommended, can have no other effect than reducing the size of the plant and the quantity of fruit. Stopping does not even augment the size of the fruit left on. Our plants, struck early in October, have never been topped, are in 12-inch or 14-inch pots, and have been once top-dressed with horse droppings already, a system about as far removed from Mr. Gilbert's small pot culture as could well be, yet all these plants are now generally about 5 feet high, and so heavily laden with fruit in all stages as almost to pull the wires from the stays. The fruit is of great size too, and we began gathering at the middle of April, and the supply now exceeds the home demand greatly. Plants sown in January now in 10-inch pots have large clusters of fruit on them, and individual fruits the size of one's fist that they will also soon colour. Plants from cuttings are a little earlier, but for carrying a heavy crop give me seedlings of the common red, which, under the same treatment, begins coming in in May and bears till December, or longer if the temperature is maintained.

Some time ago there was a discussion among your correspondents on the subject of fertility *v.* vigour. I would here just recommend those interested in the subject to test the matter with a Tomato plant. Starve one on Mr. Gilbert's principle, and feed the other. Gather and weigh the fruit in a given time, and note the result. The vigorous plants will win in a contest, only they must never be pinched back. — J. S.

NOTES ON BROCCOLI.

BROCCOLI will always form an important crop in all gardens where a constant supply of good vegetables is desired. The autumn or early winter kinds are always sure to prove highly useful, and so are the late spring and early summer ones, but there is no certainty of the mid-winter ones, as the supply of Broccoli in January, February, and March depends entirely on the weather. Those who assert there is no hardy winter Broccoli are quite right, as I have tried dozens of varieties, but I have never yet found one that would form heads in the months named when frost and snow occurred, and I have noticed that if winter varieties are kept back for a long time, and prevented from heading, in anything like season, they are apt to decay without becoming of use. Two of the best winter Broccoli I am acquainted with are Backhouse's and Osborn's, and in a favourable winter they invariably form heads from January to March, but if they are prevented from doing so during the time named, they rarely prove useful afterwards. It cannot, therefore, be said of them if they are of no use at the time they ought to be ready for table they will come by-and-by, as they do not with any satisfaction. Apart from this, however, spring Broccoli and those which are heading now, of which Sutton's Late Queen and Veitch's Late Model are excellent types, are absolutely hardy, as I never knew of a dozen plants of them to be killed, or indeed injured, by severe weather, and these may be counted hardy in growth of stem and leaves; but were they heading in 15° or 18° of frost, they would, no doubt, prove as tender in the flower as any of the winter sorts. But I do not regret very much that the frost may prevent us from having winter Broccoli, as Savoys and Brussels Sprouts are in their prime at that time, and no frost will injure them, but in April and May these are past their best, or over altogether, and were it not for the Broccoli there would be a great scarcity of open-air vegetables at the present time, as spring Cabbages are not quite ready yet everywhere in quantity. It must not be understood from this that I am against growing winter Broccoli, as I would always grow some of them and chance their coming in; but I must say that those who grow them year after year, and continually lose the greater part of them, soon get tired

of this futile labour, and I am inclined to recommend a good quantity of autumn and spring Broccoli being grown, but fewer winter ones, and more Brussels Sprouts and Savoys. If this was generally practised there would be fewer complaints about the loss of winter Broccoli and the scarcity of winter greens. There is nothing gained by sowing Broccoli too early. In many cases the seed is sown in March or early in April, and the plants are not put into their permanent quarters until June or July, but long before that time they are suffering in the seed bed from overcrowding, and by the time they are planted many of them have long spindly stems and never likely to make dwarf compact plants; whereas, if sowing was deferred until later the plants would be dwarf and stubby when transplanted, and they would retain this character always. I would rather deal with Broccoli sown at the end of April or early in May than with those sown a month or six weeks earlier, and those who are inclined to think they are late in sowing their Broccoli now will find that they are still in good season. By this time many of the best quarters in the vegetable garden are occupied, and Broccoli seed may be consigned to some inferior back corner, but nothing will be gained by this, and as some hundreds of plants may be grown while mere seedlings on a few square yards of ground, an attempt should always be made to sow in a good position. It makes little difference whether they are sown in rows or broadcast; good plants are produced both ways, but less space is required to raise a given number of plants when sown broadcast than in rows, and where ground is limited preference should be given to this plan of sowing. Excessively rich soil is not the best to sow in, as it causes the young plants to become too luxuriant, but soil of medium richness and very firm produces robust plants with close-grown roots, and these can always be planted out with much success. It is a great mistake to sow too thick, as the plants are then crowded from the first, and they become long and spindly before there is any chance of giving them more room. In cases of this kind we have known the plants to be thinned out when quite small, part of them thrown away, and only those left growing retained for use; but this is a great waste of seed and plants, and the best way is to sow thinly at first and thus ensure good sturdy plants. The seed should not be placed more than 1 inch below the surface. The best time to plant them out is when they are from 4 inches to 6 inches high. Should they be inclined to become much taller than this before the ground is ready for them, the largest of them should be drawn out and dibbled in about 3 inches apart in some open piece of ground. They can then be very conveniently transplanted from this to their permanent quarters. This is a good way of securing bushy, well-rooted plants. We have planted Broccoli in all parts of the garden, and for several years we put them out between the Potato rows before the Potatoes were dug up, but they were either so smothered up with the haulm or drawn up weakly by having so much vegetation around them that we discontinued this plan, and we have come to the conclusion that good Broccoli can only be grown when it has a clear piece of ground to itself. I do not, however, approve of making it the only crop of the year, and I am much in favour of taking an early crop of Potatoes, Peas, or something else before the Broccoli is put out. CAMBRIAN.

SHORT NOTES.—KITCHEN.

Herbs from seed—I find the most expeditious way of treating these is to sow in heat in 3-inch pots a few seeds in the centre of each pot. As soon as the seedlings are strong enough thin out the weakest and gradually harden off before planting out; this operation can be performed much quicker and with less injury to the plants if an when they have been grown in boxes.—C. R.

Hardy Broccoli.—In support of Mr. Gilbert it is only fair to say, though I too was of opinion there was not a Hardy Broccoli, that I find there is. They looked so bad after the frost I was almost afraid to go near them, but on ordering them to be dug in I learned with surprise many of them were going to give us a head. A Broccoli that survives a winter and spring such as the past should be one of the hardiest.—J. H.

KITCHEN GARDEN NOTES.

ASPARAGUS.—We cut the first dish on the 28th ult., being fully three weeks later than in the average of seasons, but now that we have had the long-desired rain, we only require brilliant sunshine, and by the end of May the season will have retrieved its character, and vegetation be just as advanced as at that date in other years. At any rate, by mid-summer there is seldom any observable difference in the average of seasons, a fact that those who have still to plant or sow Asparagus should bear in mind, and get the work off hand whilst the ground is in good condition. We did this kind of work a fortnight ago, and now we have applied a last sprinkling of salt, which whilst it manures will also keep weeds in check.

LETTUCE.—The rain started these into kindly growth, and has been favourable to our planting out good plants that were sown in frames with Carrots and Potatoes. The inevitable shallow drills are again used, the plants being put in them at from 6 inches to 9 inches apart, and all have a good watering as soon as planted. The soil is not filled into the ground line till the plants are well established, and before filling in is done a dressing of burnt ashes is scattered throughout the entire length of the drills. This is better than several soakings of manure water, even if we had time to water the plants, which we have not. The principal sowings for late summer use ought now to be made. We care for no variety for summer use other than the best stocks of Paris White Cos.

BRUSSELS SPROUTS.—We have just made our first, and main, planting on ground that has been well prepared by deep trenching and manuring. The lines—drills—are a yard apart, and the plants in the row 30 inches, and they will more than fill out the space, but we cannot afford more, and so, in order to make amends for this, we shall clear off all large leaves as soon as they manifest any tendency to decay from overcrowding; this work is necessary in any case to let in light and air. Late sowings of these I consider very unprofitable, because the plants do not grow to more than half the height of those now planted; and, therefore, it is obvious that there can only be half the quantity of sprouts; as to size of sprouts there is little to choose between those from early and those from late sowings, though, of the two, I am ready to admit the superiority, because small, of the sprouts from late sowings. But the question arises, Does the slight advantage balance that of much greater bulk from early sowing? to which I unhesitatingly answer, No. Of the two, the later sown stand severe weather best, but as the taller and earlier sowings rarely get seriously injured, it is not worth taking this view of the matter into consideration; I therefore stand by early sowing, with a view to getting the plants as tall as possible, and consequently a greater quantity of sprouts.

PARSLEY.—For three seasons prior to last we had no end of difficulty with this, as the plants died off in a most mysterious manner. Many others had, and still have, the same difficulty to contend with. After trying many remedies, as a last resource we sowed patches in various parts of the garden and in every aspect, and that sown on a north border was all that could be desired; not a plant died off, but a partial failure resulted to the sowings in all other aspects. Of course, therefore, except a very small patch on a south border, the plant will this year be confined to a north border; the ground is in preparation, and sowing will take place within a day or two. As up to four years ago we never experienced any difficulty, sow wherever we would, the cause of failure is now only explicable as being due to some insect that does not relish a northern and shaded position, and which we may, therefore, expect to get rid of by continuing to grow the plant only on this aspect.

CELERY.—The earliest plants are nearly ready for putting out, and as they have been virtually outside the lights drawn off, except when frosty for about three weeks, they will, if planted with care, scarcely feel the removal. The trenches are on the point of completion, and down the centre of the

ridges will be sown Lettuce, Radish, or Spinach. When lifting the plants we are particular to pull every weed out of the ball, as well as the small leaves or offsets that may be forming round the bottom of the plant. We thus prevent the growth of weeds and offsets, and save much time that must otherwise be given up to their removal but a very short time hence. Should the plants not move with the mass of soil we expect them to do, they will, in the absence of rain, be given artificial waterings till established. We have no fear, however, of this being necessary, as we took special care to have in the soil in which they were pricked out a large quantity of roughish leaf soil, and this never fails to attract and hold the roots.

GENERAL WORK. Staking Peas; covering up Potatoes to protect them from frost; thinning out first sowing of Turnips and doing the same to Spinach; to plant out seedling Globe Artichokes and another row or two of Cauliflowers between the rows of Peas. When the weather is suitable, to hoe between the rows of Onions, Parsnips, early Carrots, and Spinach, the seeds of which have all come up well; as Broccoli is cleared, to prepare the ground by trenching for planting on it the Strawberry plants that have been forced; to prick out in a sheltered spot Coleworts and later sowings of Cauliflower that have never been raised in heat; to guard against an attack of fly on Turnips by dusting over them wood ashes, soot, or lime. W. W.

TREES AND SHRUBS.

W. GOLDRING.

RHODODENDRONS VERSUS LAURELS.

JUST when the common Laurels were well recovered from the effects of the severe frost experienced during the winter of 1880-81, the exceptionally cold March of this year again disfigured them. In the grounds here thousands of Laurels recently appeared as if scorched, while near the lake hundreds of large bushes and trees are killed down to the snow line. The Colechian Laurel, and which with good reason was expected to be much more hardy than the common form, was five years since extensively planted on an island, but even these have been badly disfigured by the frosts. Very few, if any, Laurels, however, are killed outright, and we shall have to repeat our old method of restoring them to a presentable condition. Whole rows and breadths of strong plants are being cut off to within 1 foot of the ground, the saw being principally used, as this severs the wood without leaving a jagged surface. Thus treated, they soon break strongly, and will make good progress during the summer. Unfortunately, this young growth is of a very suppy nature, and only a moderately severe frost damages it. In every case the plant ought to be gone over next spring, and have all straggling or slightly injured shoots freely cut back, thereby ensuring a more regular growth.

As our experience is by no means singular, the question, What substitute have we for the Laurels? naturally arises, and in our case the answer is not easily forthcoming. In very many instances, however, Rhododendrons will be found much hardier, will afford equally as good cover for game, and are really more ornamental. Only a few miles from here they grow and increase very rapidly, hundreds of thousands of seedlings being annually sold to nurserymen, who buy them principally for grafting purposes. On this estate they are with difficulty established in either the woods or pleasure grounds, this being due to the clayey nature of the soil, lime also being too abundant to suit Rhododendrons. Given a fresh compost of turfy loam, and either plenty of peat or leaf soil, and they will grow well for a time, but if they do not form large bushes they are never disfigured by frosts, and usually flower abundantly. Although classed as a peat-loving or bog plant, there are at the present time many thousands of plants in this country growing healthily in nothing but loam, and they are quite at home in loam in which there is no lime. Sometimes it may be necessary to mix either peat or leaf-soil with the ordinary loam in order to give the

plants a good start, this being especially the case when they were previously growing in a peaty soil. It is the neglect of this precaution that frequently leads to the loss of strong plants of choice varieties. They are supplied by the nurserymen with close balls of fibre and soil, these serving to keep them alive for a time, but unless they can be induced to root into the surrounding soil they are sure to disappoint. Not only should they be given a good compost, such as just described, but this ought to be packed firmly about the roots, loose planting being also another sure way of killing Rhododendrons. If at all dry at the roots when received, it is advisable to soak them in a tub of water prior to planting, and in any case they ought not to be raised above the surface, or it will be almost impossible to keep them moist during the summer. Experts will transplant Rhododendrons at almost any time in the year, or even when in full flower, but they attend closely to the roots, and this I should advise less experienced persons to do, never allowing them to suffer for want of water. Doubtless the bulk of the planting is now completed, but in any instance where it has not been well done I should suggest re-planting, more regard being then paid to the requirements of the plants. The old pontium and varieties are the most easily grown, but the hybrids are far more beautiful, and it is very annoying to flower and then lose them. All cost more than Laurels, but they give much more pleasure, are perfectly hardy, and ought therefore to be most extensively planted. 1.

Somerset.

Prunus divaricata.—This is one of the earliest of all the beautiful trees and shrubs of the Plum tribe that flower in spring. Quite a fortnight ago it was in full bloom and is so now accompanied by Almonds, Peaches, and a few other species of Prunus. It is a beautiful lawn tree because of its elegant growth, the branches growing in such a way as to make a regular spreading head. There is an old tree at Kew, near the Cactus house, which every season is a great attraction on account of the profusion of its white blossoms, the more noticeable because at the time no other hardy tree is in flower. It is a Caucasian tree introduced many years ago, is perfectly hardy, and never requires attention when once planted well. There should be no difficulty in obtaining this tree at a nursery, but the fact is not one nurserymen in a dozen knows it. W. G.

The Laurel and its management. I can endorse the words of "A. D. W." on this subject (p. 378), but not only does the Laurel get neglected, but in some places it is clipped and cut to such an extreme that really it looks ridiculous, and grieves the eye of anyone having the slightest regard for the natural appearance of things. A judicious cutting back of the longest shoots, as advocated by "A. D. W.," will keep this shrub low and well furnished with foliage. I think some of the Laurel hedges would be just as effective barriers if treated in this manner, while in appearance they would certainly be a great improvement upon the close-clipped ones. If "A. D. W." was here, I am sure he would be grieved to see the Laurels at a certain place not far from where I write. It may be the owner of the place has a fancy for Laurels, for along every road leading to the house they are to be found, and are all clipped after the manner of a hedge. One road runs along the side of a hill, and would command a pretty view of the valley beneath, but all is excluded by an unnecessary Laurel barrier. The climax is reached, however, in one place, where a bank with a nice, easy slope, that might be rendered very attractive if planted in a proper way, is absolutely covered with Laurels. They might not look bad if growing naturally, but, although one cannot see an obvious reason, they are clipped into a formal, unmeaningless mass, which can be seen for a long distance, and mars the effect of an otherwise pretty landscape.—A. HERRINGTON.

Variiegated Negundo under glass.—Most hardy shrubs that are forced for indoor decoration in spring are so treated for the sake of their blossoms, but in the case of this Negundo the recommendation is the beautifully variegated foliage, which

renders it a bright and cheerful object at all times, and for greenhouse or conservatory decoration it differs so widely from the subjects usually employed as to at once arrest attention, more especially if associated with deep green-foliated plants. This Negundo is generally propagated by budding on the green-leaved form, and as the roots of this are strong and vigorous, it is often no easy matter to get the plants in reasonable sized pots without mutilating the roots in such a way as to interfere with the leafage of the plant. Of course, this simply refers to nurseries and such places where plants are largely grown for outdoor planting, as if grown for potting purposes alone the roots may be curtailed during their earlier stages in such a way that they form a compact mass, which will not be the case if they are allowed to grow freely in rich soil. On this account when purchasing it should be stated whether needed for pot culture or for outdoor planting. Those required for forcing should be potted up by November and plunged in some sheltered spot, where they may be allowed to remain till the middle of February, and if then introduced into a cool part of the forcing house and syringed occasionally, will be in leaf by the latter part of March. After they are no longer required they may be either planted out or kept in pots for another season, but in this case care must be taken that the plants do not suffer at all from want of water, and that their vigour is maintained by occasional stimulants. T.

Transplanting Evergreens. The question has often arisen, are we right in transplanting Evergreens in winter? The nurseryman must, of course, go on transplanting from September to May; he cannot stop because it is winter, on account of the extent of his work, the number of labourers being in all cases more or less limited. But in planting or improving the pleasure grounds of a large estate, it is surely worth while to ascertain the season at which Evergreens can be removed with most advantage. All my experience points strongly to two seasons—the beginning of autumn (September and October) and the end of spring (April and May). As to the former season, I would say choose that period when the new growth ceases and the young shoots begin to ripen and solidify; as to the latter, take the trees just before the new growth commences. A difficulty, however, presents itself here which it is not easy to grapple with unless the place for every tree is previously marked out. In ordinary planting the subjects required for the plantations are very various, and do not all begin nor complete their growth at the same time. Some begin and finish early, growing rapidly for a short time; others begin late, and drag on a slow growth for a lengthened period. But these do not constitute the majority; most Evergreens begin and finish their growth about the same time. But how to deal with the exceptional cases is the question we wish to settle, and in such a manner that there shall be no losses by removal, and no miserable-looking plants to mar the pleasure one has a right to look for in contemplating the results of an expenditure of money and labour. The only way out of the difficulty appears to be to mark the place for every tree, making the first move, whether in autumn or spring, when the earliest trees are in the best state for planting, filling in the spaces left afterwards as the different trees arrive at the best condition for removal. There is no doubt that many Evergreens may be transplanted in autumn, even before growth ceases, and in spring after growth commences, in such a manner as to preserve a better appearance in the immediate future than they would do if removed in midwinter. Of course, in such cases, if dry, hot weather should set in at the time or shortly after transplanting, water should be brought into free use.—W. P.

SHORT NOTES.—TREES AND SHRUBS.

Pyrus japonica.—As a shrub in an open border in the west of England, this *Pyrus* is very attractive. It flowers every year with the greatest freedom, and the blossoms remain fresh for a considerable time. The colour being of the brightest crimson makes it still more conspicuous. As our plants are confined for room, we have to cut back a good deal of the growth they make. This is done late in the autumn, but there is no doubt but that this hard pruning

increases the quantity of flowers on the spurs. I may mention that the same plants also fruit freely every season — J. C. C.

A noble drooping Horse Chestnut.—In last week's GARDEN there was a picture of a group of old Horse Chestnuts. I thought it might be interesting to you to see a photograph, taken by my daughter, of a very old Horse Chestnut tree in our garden, which, you will observe, is completely furnished down to the ground all round, and has an entire carpet of Aconites underneath it. I do not know if these drooping Chestnuts are common, but this one is the only example I know.—M. P. B.

A very pale and too small photograph of a noble spreading and weeping tree — Ed.

FERNS.

W. H. GOWER.

MICROLEPIA.

THIS family is included by some authors with the Hare's-foot Ferns (Davallias). They are characterised by their creeping rhizomes, simple

mens when grown in suspended baskets; others are more suitable for pot culture; but all of them are exceedingly graceful when planted on overhanging ledges of rockwork in a naturally constructed fernery. They grow freely in a mixture of peat, loam, and sand, in about equal proportions, a moist atmosphere, and with an abundance of water to their roots. On this account the drainage must be kept open and free; indeed, perfect drainage is essential for all Ferns, saving the few aquatic species. The following are all charming plants, deserving the attention of lovers of Ferns.

M. NOVE-ZELANDIE is the smallest kind in the family; its fronds are seldom more than 6 inches or 8 inches long; they are three times divided, ovate, acuminate in outline, and dark shining green in colour; the ramifications of the fronds are very delicate, but they are very per-

to 12 inches in length, whilst the pinnules are long and broad, tapering to a point, of a light green colour, and ornamented near the margins with a profusion of its bright red sori. This plant is one of the most ornamental Ferns in cultivation, and should not be overlooked when large-growing kinds are required. It is somewhat extensively distributed in India and Ceylon.

M. TRICHOSTICHA.—This is a warm house species, being a native of Java and various islands of the Philippine group; it forms a handsome plant, its fronds being dense, 2 feet to 3 feet in length, and about 18 inches across; the ultimate divisions are broad sessile, pubescent on the under side, and light green in colour.

M. STRIGOSA is a native of Japan, and is a most desirable species for a cool fernery; the fronds

Microlepia hirta cristata.

or pinnately-forked veins, and by their half cup-shaped involucre, which are situated on or near the margin of the pinnule, and attached by their broad bases only. The genus comprises a dozen or so species, the majority of which are to be found in cultivation, and although they are for the most part natives of tropical countries, they are found growing wild at considerable elevations; this, combined with the fact that their fronds are coriaceous or leathery in texture, enables them to be utilised in the cool fernery, although it cannot be denied that most of them attain greater proportions and form more handsome specimens in the temperature of the stove. Microlepias are readily increased by division of the rhizomes just at the time when growth commences in spring, and more sparingly from spores. Several species form handsome speci-

sistent, and last a long time when cut and placed in water; therefore they are extremely useful for button-holes, mixing with cut flowers in vases for the embellishment of the dwelling-house, bouquet-making, &c. In the naturally constructed fernery it forms an elegant object, and is seen to the best advantage when planted on a jutting rocky boulder, although it also forms a pretty specimen when treated as a pot plant, whilst no more elegant Fern can be found for the Wardian case. It is a cool-house plant, and enjoys an abundant supply of water. Native of New Zealand.

M. PLATYPHYLLA is a plant directly opposite to the preceding, having fronds some 3 feet or 4 feet in length, and proportionally broad; the fronds are three times divided, the second division being ovate-lanceolate in shape, from 6 inches

are about twice-divided, from 2 feet to 3 feet in length, and nearly a foot wide; the segments beautifully crenate on the edges, and the colour bright green.

M. POLYPODIOIDES.—This is a very delicate and handsome plant, which in its wild state is found widely distributed in India, also in the Philippine and Polynesian Islands. Its fronds are some 3 feet high, three times divided, the first division being alternate and distant; the segments are deeply divided and obtuse. It grows very robust in the warm house, but thrives well in a cool fernery, especially the forms of the species which come from Northern India.

M. HIRTA, from Ceylon and Northern India, is a variable plant, producing fronds from 3 feet

to 6 feet long, three or four times divided, coriaceous in texture, densely pubescent on the under side. The variety *cristata*, which we here illustrate, is an extremely graceful plant, its drooping habit and tasselled fronds rendering it specially useful for basket purposes. It is a native of the South Sea Islands.

The Killarney Fern. I see your correspondent "R. D.," in *THE GARDEN* (p. 382), speaks of the difficulty some have in growing the Killarney Fern well. We have it doing uncommonly well here. It is growing in a glass case, at the cool end of an ordinary rock fernery, planted in ordinary peat, and kept moist by syringing two or three times a day.—HENRY BRASIER, *Ely.*

ORCHIDS.

W. H. COWER.

SELECT FORMS OF CATTLEYA TRIANÆ.

THIS gorgeous winter-flowering *Cattleya* is extremely variable, and although the ordinary forms are very beautiful, they are too numerous, and not sufficiently distinct to receive varietal names. Those, however, which are specially remarkable for their size and intensity of their markings have deservedly received names by which they may be identified in gardens and distributed commercially. A few of the most distinct are *Osmani*, in which the sepals and petals are of a uniform rich purplish mauve, lip large, bright purple, with a broad frilled border of pale mauve, the whole of the throat being golden yellow. *Ernesti* is a very large form; the broad sepals and petals are lilac-mauve, tipped with magenta, the same colour running in a slightly flaked stripe down the centre of the petals, the front lobe of lip very large, rich crimson-lake, becoming more intense towards the base, where it meets the deep orange yellow, which suffuses the whole throat. *Dodgsoni* is a chaste and beautiful flower with pure white sepals and petals, lip deep violet-crimson margined with pink, and an orange-yellow throat. *Russelliana* is one of Baron S Schröder's gems; its flowers are, in the sepals and petals, white, suffused with a beautiful tinge of rose; the lip is beautifully fringed, front lobe intense crimson-magenta with orange throat. *Symeana*—sepals and petals deep blush, lip intense velvety crimson with deep orange-yellow throat. *Backhouseana* produces very large flowers with pink, or blush-pink, sepals and petals, the front portion of the lip being suffused with bright magenta, whilst the throat is pale yellow. *Leeana* is one of the giants of its race, the flowers measuring 7 inches and upwards in diameter; the sepals and petals are rosy lilac, front lobe of lip large, magenta-mauve, margined with the same colour as the petals; the throat is open and streaked with orange. *Alba*, as its name implies, is pure white, the whole of the flower being devoid of the slightest tinge of colour, saving a stain of yellow in the throat. Many forms of a white flower in which the lip is tinged with lilac have the name of *alba* erroneously attached to them; these forms are not scarce; the true plant, however, is by no means plentiful. *Corningi* is another chaste variety, the sepals and petals being white, slightly flushed with pale rose, lip white blotched in front with orange. *Formosa* has a large bold flower, sepals and petals soft flesh colour, the large fringed lip being magenta-rose, with orange throat veined with a much deeper shade of orange. *Williamsi*, blush-pink in the sepals and petals, the latter being veined along the centre with pale magenta; the frilled lip is crimson-purple—this

colour passes far into the throat and over the side lobes; the throat is only slightly blotched with yellow.

Cattleya Skinneri at Beckenham.—One of the finest displays of this rosy purple-flowered *Cattleya* perhaps ever seen in this country is now to be seen in the garden of Mr. J. Goddard, Elmer Lodge, Beckenham. On the occasion of our visit some 600 or 700 flowers were expanded, one plant bearing upwards of sixty, whilst some of the single trusses bore a dozen blooms. These plants were imported a few years back by Mr. Goddard, and were then small pieces. Mr. Reed, his gardener, attributes his success with *Cattleya Skinneri* to the fact that the plants have been exposed to the full light on all sides all the year round. The temperature during the growing season has been allowed to run up high with sun-heat, shading the plants slightly from the direct influence of the sun, and allowing them a free circulation of air; at this time they have a moderately free supply of water to their roots, but when growth ceases the water supply is gradually decreased until just sufficient only is given through the winter to keep the pseudo-bulbs and leaves from shrivelling. During the resting season the temperature is allowed to fall as low as 15°. Those who have hitherto been unsuccessful with this beautiful species cannot do better than subject their plants to the cultivation here given, by which Mr. Reed has attained such remarkable results.—G.

Orchid prices. On Tuesday and Wednesday, May 3 and 4, Messrs. Protheroe and Morris disposed of some of the duplicate specimens from the celebrated collection of Mr. Lee, Downside, Leatherhead. Buyers were numerous and competition was keen. The following are a few of the most notable prices realised: *Cattleya Trianae Atalanta*, £23 2s.; *C. lobata Boothiana*, £14 11s.; *C. Trianae Percivaliana*, £25 5s.; *Masdevallia Demoussiana*, £32 11s.; *Cattleya Trianae Dayana*, £56 11s.; *C. Trianae Thomsoni*, £23 2s.; *C. Trianae Emperor*, £16 18s.; *C. Trianae alba*, £12 12s.; *C. Trianae Colemani*, £21 3s.; *C. Trianae Backhouseana*, £13 13s.; *Lælia elegans Wolstenholmei*, £12; *Cattleya Skinneri oculata*, £73 10s.; *C. Amesiana*, £94 10s. and £68 5s.; *C. calumnata*, £17 17s.; *Cypripedium acanthum*, £16 16s.; *C. microchilum*, £25 18s.; *C. Wallisi*, £31 10s.; *Dendrobium Phalænopsis*, £52 10s.; *Cypripedium Morganii*, £178 10s.; *Cattleya Fausta*, £11 11s.; *C. labiata*, £37 16s. and £26 5s.; *C. Trianae Emiliae*, £32 11s.; *Coleogyne cristata alba*, £57 15s.; *Vanda tricolor*, £13 13s.; *V. planilabris*, £11 11s.; *Cattleya Trianae Osmani*, £105, £94 10s., and £63; *C. Trianae Leeana*, £139 10s. and £105; *Oncidium superbiens*, £23 2s.; *Cypripedium acanthum superbum*, £28 7s.; *Odontoglossum crispum delto-glossum*, £13 13s.; *O. macrospilum*, £22; *Cattleya Trianae Dodgsoni*, £73 10s.; *Cymbidium giganteum*, £23 2s.; *Maxillaria Sanderiana*, £18 18s.; *Saccolabium Harrisonianum*, £162 15s.; *Lælia bella*, £189; *Cypripedium vexillarium*, £33 12s.; *C. grande*, £68 5s.; *C. tessellatum porphyreum*, £78 15s.; *Cattleya Skinneri alba*, £33 12s.; *Cymbidium Lowianum*, £21; *Angraecum caudatum*, £37 16s.; *Lælia elegans Turneri*, £31 10s.; *Odontoglossum Hrubyanum*, £29 8s.; *Masdevallia Harryana rugosa*, £18 6s.; *Cypripedium selligerum majus*, £41 2s.; *C. Arthurianum*, £23 2s.; *Vanda suavis*, £21; *Saccolabium Heathii*, £137 10s.; *Cattleya exoniensis*, £105; *Cypripedium Stonei platytenium*, £325 10s.; *C. Leeanum superbum*, £32 11s.; *Lælia purpurata Williamsi*, £67 18s.; *Lælia grandis*, £94 10s.; *Cattleya Mardeli*, £41 2s.; *Lælia Veitchiana*, £36 15s.

SHORT NOTES.—ORCHIDS.

Trichocentrum orthoplectron—This is a small-growing plant, which requires to be grown on a block of wood. It is a rare plant; the leaves are thick and fleshy, and the short drooping spikes bear a single large flower; the sepals and petals are cinnamon-brown, and the large flat lip is rich crimson-lake with a yellow disc. It blooms in the month of October, and should be grown in the *Cattleya* house.—G.

Odontoglossum luteo-purpureum.—From the garden of Mr. De B. Crawshaw, Rosefield, Sevenoaks, have come blooms of the above Orchid, a handsome species

found with *O. crispum*; with it also came a small form of the latter, named *cuspidatum*, described by Reichenb. et in "Xenia." This is one of the most variable of *Odontoglossums*, as we have in our own collection a dozen varieties, selected from 300 imported plants of *O. crispum*.—J. B.

GARDEN DESTROYERS.

REPORTS ON INSECTS INJURIOUS TO ROOT AND CERTAIN OTHER CROPS.*

ANOTHER of Mr. Whitehead's reports on injurious insects has just been published by the Agricultural Department of the Privy Council Office. These pamphlets, though called reports, are really a series of monographs on injurious insects, and not, as is the case with Miss Ormerod's reports, on what has been noticed in connection with certain insects during the past year. Mr. Whitehead has already written reports on insects injurious to Hops; to Corn, Grass, Pea, Bean, and Clover crops; to fruit crops; and this fourth report deals with insects injurious to root and certain other crops, namely, Mustard, Rape, Cabbages, Onions, Carrots, and Celery. These reports are models of clearness and conciseness, and their very moderate price brings them within the reach of everyone in a position to make use of them; they are printed in clear type on good paper. At the beginning of a monograph, as the account of each insect is called, is a figure of the insect in its various stages, most of which are very good. Many of them are taken from Curtis's "Farm Insects." Then follows some remarks on the habits of the insect; then an account of its life history, the best methods of preventing its attacks, and the best remedies to be used when an attack has commenced. These items of information are given under different headings, so that they can be found immediately they are wanted. It is curious that in the present report all mention of millipedes should be omitted. It is true these reports only purport to deal with insects, but red spider, the Black Currant mite, and the ear coekle worm, which are no more insects than millipedes, have already been commented on. Millipedes are such injurious creatures to many crops, that they certainly should not have been left out. The first insect mentioned is a beetle (the night-feeding ground beetle, *Steropus malidus*), which until comparatively recently has always been considered as a carnivorous insect; but there seems no doubt now that it attacks young Mangold plants. It is a very common insect, and during the day may generally be found under stones, rubbish, &c. The grubs or larvae are said not to injure plants, and from the formation of their jaws one would certainly imagine that they are carnivorous. If it is, it must be of great service in destroying smaller grubs, &c. As regards the effect of frost on insects, Mr. Whitehead very truly says (p. 11):—

One hears frequently, "Splendid frost! it has got deep into the ground—will kill the insects." It is a common error to imagine that frost invariably kills insects either in the perfect, the egg, the larval, or the pupa states. Very many insects are so constituted as to be frost-proof. This is a provision of Nature. Many are overtaken and killed by abnormally early or abnormally later frosts before they can assume the form in which they can naturally resist them, but, as a rule, insects are unharmed by ordinary winter frosts. As a fact, chrysalides which have been exposed to sharp frosts, and frozen so hard that they would snap asunder like pieces of stick, nevertheless have preserved vitality.

It is, I think, being proved more clearly every year that great care should be taken when about to distribute stable or farmyard manure over land that various insects should not be sown broadcast at the same time. Manure heaps should not be allowed to remain in fields until all the goodness has been washed out of them into the nearest ditch, as is commonly the case. Manure when thus impoverished is more likely to harbour insects of all kinds which could not exist in the greater heat and pungency of a heap in proper condition. The proper rotation of crops is a great safeguard against the too rapid increase of some insects. If the same crop is grown year after year on the same land, or a certain piece of ground is used season

* "Reports on Insects Injurious to Root and certain other Crops in Great Britain." Prepared for the Agricultural Department, Privy Council Office, by Chas. Whitehead, Esq., F.L.S.

after season as a seed bed for the same plant, insects which attack such crops have a much better chance of establishing themselves in the soil. Twenty-two insects in this report are fully described with their life history, &c. These descriptions, as I have already mentioned, are given in a particularly clear and terse manner. I can recommend this pamphlet most warmly to all cultivators of plants either in gardens or fields as a most useful publication; its very moderate price (5^d.) places it within the reach of all. G. S. S.

Vine roots diseased.—I send you a few Vine roots for your opinion. I am told they are infested with *Phylloxera vastatrix*.—J. L.

* I can find no trace of *Phylloxera* on the Vine roots, but they are attacked by the bull mite (*Rhizoglyphus echinopus*), which is a more frequent pest on Vine roots than most persons are aware of. These mites are most difficult to eradicate. I know of no other means than cutting out the injured roots and washing the others with a strong solution of sulphate of potassium—3 ozs. in half a pint of water—and taking care to remove any earth which might possibly contain any of the mites. It is easy enough to write this, but very difficult to carry out effectually.—G. S. S.

Grubs on roots of Strawberry plants.—We send you samples of Strawberry plants infested with grubs, and would thank you to give us information about it, its name, and best means of removing the plague. W. L. & SON.

* The grubs attacking the Strawberry roots are those of the black Vine weevil (*Otiorhynchus sulcatus*). This is a most troublesome insect, both as a grub and beetle. I do not think anything can be done when once the plants are attacked, except pick the grubs out from the roots. The best mode of keeping this insect in check is to kill the parent beetles, which are black, stout, and about half an inch long. They are somewhat sluggish in their movements, generally remaining hidden during the day, coming out after dark to feed, which they do voraciously on the leaves of Vines and many other plants, gnawing great notches in them. If you can find the plants they are feeding on, place them on a white sheet, and when dark suddenly throw a bright light on them; this startles them, and they fall, feigning to be dead. A sharp shake to the plant often helps matters.—G. S. S.

Eucharis mite.—I enclose three *Eucharis* bulbs which I fear are affected with mites. I should be pleased to know your opinion of them.—A. J. HUNNARD.

* Yes; your bulbs are affected with the *Eucharis* mite. The only way to get rid of the pest will be to burn all the stock you have, and start afresh with clean bulbs.—ED.

BOOKS.

HORTICULTURAL BUILDINGS.*

THE author of this volume says: "Up to the present date no book has existed from which a gentleman could obtain, in a complete concise form, reliable information to assist him in deciding what garden structures would best suit his requirements, nor one in which an architect could see just those constructional and mechanical points which should be decided by the horticulturist, or in which a gardener could find details beyond his province, but with which he should be acquainted." And the author, we are to infer, has aimed at supplying this want. If so, we can only say, after having carefully, though interruptedly, perused the book from beginning to end, that he seems to have succeeded very well in his endeavour, and even to have done considerably more than the title implies. We should read his book more comfortably if the clerk and printer had been more sparing of their errors, but in other respects we can cordially recommend it to anyone who contemplates erecting, or is likely to be called on to design, horticultural glasshouses. Certainly if we were to examine it in detail, it would be necessary to dissent from the author's conclusions on various points, but none of them are of supreme

* "Horticultural Buildings: their Construction, Heating, Interior Fittings, &c., with remarks on some of the principles involved and their application." By F. A. FAWKES. London: Swan, Sonnenschein & Co.

importance, and altogether they are but few, considering the scope of the book. W. SIMMONS.

The Lindley library.—Owing to the death of Mr. Thomas Moore, the number of trustees (other than the official ones connected with the Royal Horticultural Society) had become reduced to two, viz., Dr. Hogg and Dr. Masters, the only survivors of the original seven. Under these circumstances it became, in the words of the trust deed, "a moral obligation" to fill up the vacancies. This has accordingly been done, by the election of three new trustees, in the persons of Mr. William Carruthers, President of the Linnean Society, Keeper of the Botanical Department, British Museum; Mr. George Maw, F.L.S., of Kenley, Surrey; and Mr. Harry J. Veitch, F.L.S., of Chelsea. The official trustees are the treasurer and secretary of the Royal Horticultural Society for the time being. Though connected in a measure with the fortunes of the Royal Horticultural Society, the library is essentially an independent institution, and is open to the general public as well as to Fellows of the Society, under proper regulations, and under certain conditions books are allowed to be borrowed. The funds at the disposal of the trustees are, unfortunately, too small to allow of much more than the purchase of periodicals, while the room in which it is lodged is so inconvenient of access, that the utility of the library is seriously impeded. In any change of site or other circumstances connected with the Royal Horticultural Society, the question of adequate accommodation for the library and its proper maintenance must have earnest consideration. In the meantime, donations of books or of funds will be thankfully welcomed by the trustees.

SOCIETIES AND EXHIBITIONS.

MANCHESTER ROYAL BOTANICAL AND HORTICULTURAL.

THE second of the society's spring flower shows was held on Friday, April 29, in the Town Hall. In connection with it was the annual exhibition of the northern section of the National Auricula Society. Better examples of the Auricula were never staged in Manchester. The chief honours fell to the energetic secretary of the society, the Rev. F. D. Horner, who carried off first honours in every class. Close upon Mr. Horner's followed admirable collections from Mr. William Bolton, Warrington; Mr. Arthur Potts, Hoole House, Chester; Mr. Henry Wilson, Halifax; Mr. Pohlman, Halifax; Mr. Brockbank, Didsbury. Groups of alpine were also noteworthy from Mr. Stelfox and Mr. Buckley, Stalybridge; Mr. Heys, Northen; and Mr. Shaw, Moston. In Primulas, the premier honours were taken by Mr. S. Barlow, of Stakehill. The most delightful circumstance connected with the display made on the present occasion is, that while the fancy kinds have had protection from the weather, the plainer and hardier ones were all dug up out of their surroundings of green Grass in Mr. Barlow's garden at Llandudno. Mr. William Brockbank also made an exceedingly beautiful show. Mr. Thomas Walkden, of Sale, sent a beautiful group of Primulas, conspicuous being the old dark crimson double, now becoming so rare near Manchester. Next to the Primulas in importance and effect on the present occasion were the Daffodils. Two magnificent displays of Narcissi were made, the first, comprising about fifty large clusters, from Messrs. Dickson, Brown, and Tait; the other, constituted of about a hundred varieties, from Messrs. James Dickson and Sons, Chester. The Chester lot included some capital examples of the variety Sir Watkin. There were some admirable displays of stove and greenhouse plants, the entire space beneath the organ being occupied by the grand collection from Mr. Joseph Broome. So brilliant a contribution could not possibly go unrewarded, and the society's jubilee gold medal was worthily awarded. Excellent miscellaneous groups were staged by Mr. B. S. Williams, Holloway; Messrs. F. W. and H. Stansfield, Sale (these chiefly hardy plants); and Mr. John Hooley, of Edgeley. A little lot of curiosi-

ties and rarities from the society's gardens at Old Trafford was very interesting. The following awards were made by the committee. First-class cultural certificates—*Polyanthuses* and *Primroses*, Mr. H. Walkden, Sale; *Narcissi*, Messrs. Dickson and Sons, Chester. *Miscellaneous stove and greenhouse plants*, Mr. B. S. Williams, Holloway. *Herbaceous and alpine plants*, Messrs. F. and H. Stansfield, Sale. *Miscellaneous stove and greenhouse plants*, Mr. John Hooley, Edgeley. *Cut blooms of Hyacinths and Narcissi*, Messrs. Dickson, Brown, and Tait.

LEEK AURICULA SHOW.

THE second exhibition of Auriculas and other spring flowers, held at the Town Hall on Saturday last, showed a vast improvement upon its predecessor. Not only were the exhibits more numerous and better grown, but the interest was distinctly greater, and promises well for the future of the society. Amongst the grey-edged, Col. Champneys was the winning variety, and those staged by Mr. H. W. Nixon were very much superior to any others in the class, although Apollo was greatly admired. In green edges, Prince of Greens, Duke of Cambridge, and Duke of Wellington were to the fore in the order named, the winning plants being really well-grown specimens. The white-edged varieties, though not so numerous, were also meritorious, Acme, shown by Mr. B. Flanagan, being very fine, and deserved the premier position accorded to it. Self formed a strong class and keen competition, the first prize going to Negro and the second to C. J. Perry, shown by Messrs. H. W. Nixon and M. Carding respectively—undoubtedly the best of the eighty shown. The prize for the best seedling was awarded to Mr. W. Barnfather for a very fine dark purple self. Mr. Nixon was first in the alpine class with Mercury, the same grower also taking second and third with Mrs. Llewellyn and Mrs. Meiklejohn. Mr. M. Carding staged about twenty varieties of garden alpine, which were greatly admired. Cheshire Favonite bore down all opposition in *Polyanthuses*, Messrs. J. Brunt, J. Garner, and T. Lea being the successful exhibitors. *Primroses* in pots were also well shown. The feature, however, of the show was a magnificent collection of fifty-five varieties of Daffodils staged by Messrs. Barr and Son, of King Street, Covent Garden, and throughout the day a crowd surrounded their stand, amazed by the dissimilarity and splendid growth—"a host of golden Daffodils," truly. Messrs. Dickson, Brown, and Tait (Manchester), Mr. T. S. Ware (Tottenham), Messrs. James Dickson and Sons (Chester) also exhibited excellent collections, as did Mr. M. Mellor, of Leek. The arrangements were admirably conceived and well carried out by Mr. H. W. Nixon, the honorary secretary. The profits of the show, which amounted to about £10, will be given to the Leek Cottage Hospital Jubilee Fund.

WOODS & FORESTS.

"YORKSHIREMAN."

FORESTRY NOTES.

MISMANAGED PLANTING.—I am convinced that much of the ill success that attends the formation of young plantations, especially of such ticklish subjects as the Corsican Fir and its like, is due to mismanagement and want of forethought and preparation. A Scotch Fir even, no matter how young and vigorous it may be, will die if not taken up at the right time with sufficient roots, or if it be kept long out of the ground between lifting and planting again. Now is the time to take measures for planting, so far as setting out and preparing the ground are concerned, after which it will be almost time to take out the holes so as to be able to begin in September and October. The dilly-dallying noticeable on some estates is fatal to successful planting. Sometimes the delay is the fault of the forester, and sometimes of his employer. On one large estate I was told not long since that as late as March the proprietor had just decided what he would do, and at once ordered about one hundred thousand trees, of all sorts, to be forwarded at once, and which his forester was at his wit's-end to get in in anything like a safe and reasonable time with the means at his disposal. As he observed to the writer, what can the woodman do under such circumstances? That lot was planted in a dry time, and as the trees have not had sufficient rain to moisten the roots since, the consequences may be surmised; they will perish by the acre. The severe frosts in March, followed by the late scathing east wind, have had a most disastrous effect on all late planted trees; whereas October planted stock of all descriptions is in good condition. I never saw more promising Corsican Firs than those planted early last autumn; hardly any have gone back. I was told not long since of the "forest-tree" man in a noted nursery in the north declaring in emphatic language that he wished "the Corsican Fir had never been born," as the half of them at least died after transplanting, subjected to the same treatment as others. This tree is much sought after now, and nurseries are hurrying up stock of it, but their losses, I hear, are appalling. It will grow, however, if lifted with reasonable care in September or October and planted at once. If allowed to be kicked about in bundles like fagots, as is too often the case in nurseries, it may almost as well be burnt at once.

We know of cases where 18-inch plants of the Corsican, put out last October on a moor direct from a strange nursery, not one hardly of which have failed. They look green at this date, at least, and have not that browned appearance so common at this time of the year in those that are going wrong. Trees put out in former years look equally well, and promise a grand lead this season. All these trees were lifted and loaded off from the nursery under the supervision of our own men, and I will venture to say the roots they had with them were twice as long and as numerous as those lifted by the nursery employés by themselves. The head men in a large nursery cannot look after the execution of every order sent to them, and the result is that the work is left to labourers, who know little, and care less, as to what becomes of the trees after they leave their hands. Firs of all kinds suffer worst; hence the importance of buying these when small and cheap, and growing them on in the home-nursery, and buying the deciduous trees that are not so sensitive. Reputed frequent transplanting is not worth anything if the roots are not there. I would give more for

one Corsican Fir lifted from the home-nursery, although it might not have been transplanted for several years, than I would for a dozen sent from a distance, lifted and despatched in the ordinary way. And the same holds good with Larch.

Then as to planting. The slit method of putting the trees just under the soil may answer under favourable circumstances, but all young forest trees have naturally a tap root, and whether they may have lost it or not, I would, if I could, plant all on the dibber principle, just as Cabbages are planted. One deep, narrow hole, and the roots let straight down into it and wedged tightly up to one side is the way to do. The tree, come drought or come frost, has its main roots then beyond the reach of either, and is sure to do well. A long, narrow spade put straight and deeply down, lifting out just as much earth as will let the roots readily in, is the plan in pit planting. I hate to see a gaping, shallow hole, and always feel inclined to fall foul of the man who makes it, because he is sure to drop the plant in the centre, filling in on all sides, and treading round the plant with his feet like a baker. I do not regard what foresters call the notch system of planting as having anything to recommend it but its cheapness. Very small trees on good, clean land may succeed well enough so planted, as they have few roots, but with good plants it is different, and the more carefully they are fixed in the soil with their leading roots well below the surface, the better. The advantages of spreading the roots out evenly under the notch are imaginary. In plants from the nursery there are few or none to spread, and what prongs and roots there are are better wedged in vertically and firmly. They will be near enough to the surface under any circumstances, and are better spread vertically than horizontally.

THE CONIFERE.—The list of these, like the fruit tree, Rose, and vegetable lists, is encumbered with varieties, sub-varieties, and synonyms, and I believe I am quite within the mark in stating that if four-fifths of the lot were consigned to one good bonfire, they "never would be missed" from the garden or wood. According to the latest manual on the Conifere, there are some 300 or 400 species and varieties known or grown. How many of these have been established in our woods and found worth keeping could probably be counted on the fingers of both hands, or a little more. These consist of the Scotch Fir, the common and Silver Spruce, the Corsican and Austrian Firs, the Wellingtonia, Pinus excelsa, Deodar, Cedar, Douglas Fir, Nordman's Pine, and a few others, and if the really best timber-producers of these were selected the list would probably be reduced by a half. I do not know that the gross results of our Conifere knowledge and experience could be more accurately stated. If we had planted woods instead of carriage drives and garden plots with the so called new varieties, our experience might have been different, but the above is about the sum total at present. The hardest Conifere only will endure the "single specimen" system of culture in this country, because our cold winds and fitful thaws and frosts kill them standing alone; but the real way to test any Pine or Fir planted either for timber or landscape effect, or both together, is to plant them in masses, and the bigger the better. I have no doubt in my own mind that if the Wellingtonia, for example, had been originally planted in good-sized groups and pretty closely together, it would have produced good useful timber by this time of such a bulk and quality that the Larch could not approach. I think the same in regard

to the Deodar, Pinus excelsa, Austrian Fir, and, above all, the Corsican Fir. Bad as the Wellingtonia is for standing cold winds in inland situations, I notice that it never "loses its head," i.e., its top. It continues to grow taller fast, but the side branches dwindle and die. In isolated positions the common Spruce, Nordman's Fir, and others behave in the same manner, suggesting plainly that they like the shelter of each other, and should be planted in masses. In future, therefore, instead of forming Conifere grounds of single trees, I would recommend gentlemen to plant good groups of such sorts as they feel disposed to try, to make their plantations their Conifere gardens, and to plant glens and ravines instead of mountain tops. In all landscapes I have seen, painted or real, I notice that it is almost invariably the precipitous sides of the valleys on which the Pine forests grow, and that the best timber is at the bottom. A traveller, who has been much abroad collecting seeds of the Conifere tribe, tells me that in Japan, where such fine forests of the Cryptomeria and other Pines exist, the trees look as if they had begun at the bottom of the valleys first and extended upwards, and that all the finest timber was produced in such situations; the narrower and steeper the gorge the finer and straighter the timber.

LORD ABERDEEN'S PINE.

(PINUS PINASTER HAMILTONI.)

THIS is one of the best and most desirable of the many varieties of Pinus Pinaster. That it is both a distinct and pretty tree, and one that is well fitted for planting extensively in almost any part of the British Isles, I am fully convinced. I have seen trees of this variety growing on a sandy hill where gravel for road-making is oft procured, and more than one of our 'cute nurserymen have been led thither only to express astonishment at the finely rounded heads, bright healthy appearance, and well developed stems of this by-no-means common, yet beautiful member of the Pine family. In my own opinion Lord Aberdeen's Pine is a most ornamental tree—a decided advance in this way over the normal form—with a conspicuously rounded head, a well branched stem, and an abundance of pale green, but very desirable foliage. Combined with this we have its great hardihood, its love for breezy situations, even putting on its best form in the teeth of the blast, and its capability of thriving even in the poorest of soils—sand and gravel.

For the introduction of this Pine we are indebted to Lord Aberdeen, who in 1825 sent it from the neighbourhood of Nice, where it had been found by M. Risso, but sparingly, and at no great distance from the town. The principal points of difference observable in this variety are the shorter leaves, smaller cones, and better furnished stem, the branches having a greater inclination to remain in a healthy condition on the stem than is the case in the typical Pinaster. In most works treating on Pines the leaves of Lord Aberdeen's variety are said to be of a paler green than in the normal form, but this I quite failed to see, probably from the specimens I examined being in the most luxuriant health and fully exposed in every way. They are, it is true, and this is very observable, both broader and shorter, and thus impart to the tree generally a more compact and massive appearance than is noticeable in the majority of specimens of P. Pinaster. The cones are much shorter than in the typical Pinaster, of a lighter colour, and differently shaped, being nearly ovate instead of truly conical.

Little hesitation have we in recommending this variety as fully superior to the ordinary form for ornamental purposes, and as it is of free growth and perfectly hardy may be planted for shelter even in very exposed parts of the lawn or park. The branches grow thick and strong, like those of an Austrian Pine, while the great abundance of foliage renders the rounded head compact and firm,

and well fitted for doing battle with even the fiercest storms. It is, in truth, a much refined Pinaster, the massive, easy appearance of the latter being substituted by a somewhat dressy and formal style of growth in Lord Aberdeen's tree.

Sir Charles Lemon's Pine (*P. Pinaster Lemoniana*) is another very distinct form of the Pinaster in which the cones are only about 2 inches long, produced singly and, in contra-distinction to those of the typical tree, at the ends of the shoots. It is questionable, however, if this variety will retain its characteristics under the best method of cultivation, for in a specimen supplied by Sir Charles himself to the Royal Horticultural Society's garden, at Chiswick, the cones had in a few years increased to nearly twice the size of those described and figured by its finder, although they were still produced singly and at the termination of the branches.

The appearance of a medium-sized tree of this variety is that of a dwarfed, ill-grown Pinaster with a crooked stem, the branches thickly arranged and twiggy, and the leaves short, or usually about 3 inches in length. The cones are fully 2 inches long by 1½ inches in diameter at the thickest part, and have unarmed scales. So far as I can find out, this variety originated, or was, at least, first noticed at Carelew, in Cornwall, by Sir Charles Lemon, and who contributed to the Horticultural Society (1835) an account of it, and which, at the time, attracted a considerable amount of attention and discussion. There is, likewise, a variegated form of the Pinaster, but in the specimen brought under my own notice this did not appear to be either constant or regular.

A. D. WEBSTER.

TRADE RINGS.

ARE growers themselves altogether free from blame in this matter? I do not mean that the bulk of producers go intentionally wrong, but it is certainly open to question whether combinations are not fostered by the manner in which sales are effected. Does it not often occur in this way? A considerable felling has taken place or has been decided upon. This is of a similar character and suited for a similar purpose, and the price based upon its value at the point of consumption is nearly as easily ascertained as that of consols. To work this out at the least possible cost it is clear that one individual or one firm should have the handling of it in preference to half-a-dozen, and my experience has been that an individual or firm, when treating for a lot of this sort, will touch the highest market figure in order to command the whole lot. In such a case a combination could not occur, and would be unnecessary if it could. On the other hand, the owner elects to submit his timber by public auction or tender. This brings a number of merchants together from considerable distances and at a considerable expense. It is perfectly clear that all cannot be buyers, and the hope of the seller is that competition will thus be induced and the price be run up. When this happens, the owner of course rubs his hands with glee, and the would-be buyers return sadder, but wiser men; and from this, in course of time, they learn to protect themselves by means of combinations or rings. I will not go so far as to assert that in every case as good a reason as this could be given for combined action, but it cannot be denied that it is largely a means of self-defence. The best method of destroying trade rings is to remove the cause of them, and this, in the majority of instances, can be done by selling privately to a reliable firm and making the interests mutual. If the seller elects to bring ten times as many men together as is necessary to buy a given lot of timber, he, of course, must stand his chance of being out-manoeuvred. It may be objected that in selling privately there is no competition, and the merchant has it all his own way. This, however, is not so, as if one merchant insists upon taking an unfair advantage, there are always plenty who are ready to meet a seller on fair terms. In sales of a miscellaneous character the conditions are different, and an auction often brings the best results, and for the simple reason that the lots are generally small, and consumers can buy direct without the intermediate

merchant. At sales of this kind it is very seldom that rings do much damage to the vendor's interests. As I have said, my recipe shortly is—sell large lots which consumers cannot touch to merchants by private treaty, and small miscellaneous lots by auction if you like.

D. J. YEO.

PRUNING AND POLLARDING TREES.

POLLARDING, or severely cutting in the branches of trees, is not a practice to be generally recommended; still there are instances in which it is found to be absolutely necessary. In many small places the originally planted hardwood trees, such as Oak, Ash, Elm, Beech, Lime, Horse Chestnut, &c., have been allowed to go on increasing for a series of years, frequently interfering with each other, and often rendering such gardens close and unpleasant; nevertheless, no reason, however urgent, will induce the proprietor to allow any of them to be removed, perhaps owing to all of them being finely developed specimens. This is a feeling with which I fully sympathise; but for the consolation of those who, from dire necessity, have to part with such specimens, I would offer the following observations. A case came under my notice two or three years ago where some large hardwood trees standing near a boundary wall, with their tops overhanging a public road, had from necessity to be reduced or removed altogether; reduction was finally resolved on, and carried out during the winter. The chief trees operated on were Ash, Beech, Wych Elm, and Horse Chestnut. All were wide-spreading trees, and between 10 feet and 50 feet in height. The largest specimens, at 3 feet above the ground, measured in circumference as follows: Ash, 6 feet; Beech, 5 feet 1 inch; Elm, 8 feet 5 inches; and the Horse Chestnut, 5 feet 5 inches. All were cut down to within 18 feet or 20 feet from the ground, and portions of the main branches, averaging in length from 3 feet to 4 feet, were left in such a manner as to give the denuded trees a regular outline; they were then carefully operated upon according to the strictest rules of forestry as regards ornamental trees, all sloping cuts smoothed and darkened over. During the first year after the operation, standing as they do side by side, they certainly presented, as might be expected, a somewhat bare appearance, which would not have been so much the case if only alternate specimens could have been operated on. After the first year, however, they annually improved, so that now their appearance is really pleasing to the eye, the stumps of the branches left being clothed with numerous young and healthy twigs.

During the first year the Ash made growths 4 feet long, during the second 3 feet to 4 feet, and during the third about 2 feet. The Elm made from 2 feet to 3 feet during the first year, 3 feet to 4 feet during the second, and from 4 feet to 5 feet during the third. In the case of the Wych Elm it is necessary, in order to secure a tree with a good outline, occasionally to prune in a little the strongest of the newly made branches, without which it is apt to have a few of its leaders taking a somewhat horizontal direction, to the detriment of the others. The Horse Chestnut's growths averaged about 2 feet long during the first year, from 2 feet to 3 feet during the second, and about 2 feet during the third. The Beech made about 3 feet growths during the first year, but by no means numerous, 1 foot to 2 feet during the second, and 18 inches during the third. I was rather surprised to see the Beech tree putting out any young twigs at all, as it generally does so with reluctance. It made its largest growths during the first year, a circumstance probably owing to the existence of extra sap then in the stem, the after-growths being much smaller.

After the trees had been cut over, and the branches removed, all ought to have received a coat of fresh soil over the roots. This would have been the means of greatly improving them, particularly the Beech; indeed, every tree and shrub, when pruned down and reduced, ought to be thus treated, more particularly large evergreen shrubs, which in many cases die from the want of this necessary precaution. This is often observable in the case of large Portugal Laurels, Hollies, and Yews, as, owing to their close

ness, the roots are generally near the surface, and liable to be injured by frost or exposure to the sun. I may also remark here that as the bark of the Beech tree is of rather a hard, dry character, it would be much in its favour, after being headed down, to have the head occasionally syringed, particularly if the weather is at all dry and warm.

Although the particular trees alluded to have only been three years cut in, when in foliage, they certainly have, as has just been stated, a very good appearance, which warrants our recommending the practice in places where trees would otherwise require to be altogether removed; in some situations, too, only every alternate tree bordering a property would require to be thus pollarded. In the case of Elm trees standing within a boundary wall, I have recommended every alternate tree to be pollarded and branch-pruned as described, and the result in all cases where attention has afterwards been paid to them has been satisfactory, the pollarded specimens filling up in a creditable manner the spaces between the branches of those left untouched.

The Lime tree, even when of large size, stands with impunity "topping" and branch-cutting, and the Ash, English Elm, Poplar, and Willow I have often seen so treated, and with success. It is well known that the Beech, in a young state, will stand any amount of cutting; but I never recommended large Beeches to be so treated till I observed the progress made by the one referred to. My object in making these remarks is to point out to those individuals who are unnecessarily scrupulous about the thinning of outside trees, that if they can put up with the somewhat bare appearance of them for a short time, such pruned trees in a year or two, if properly cared for, become quite as ornamental even at forty or fifty years of age as they were when only twenty years old.

J. M.

Seasoning timber.—Trees, immediately after they are felled, unless they have been previously killed, contain a great deal of moisture, and are, therefore, unfit for use until they undergo a seasoning process. This is simply the evaporation of the water, which if allowed to remain in the tree would ferment and decay, and if dried out too rapidly would leave the timber brittle, because the gum and other matters in the wood would evaporate with the water, instead of gradually assimilating with the fibres, and tending to bind them together as is the case where the drying is properly conducted. How to accomplish this is the principal thing, and there are many means of doing so. Some people say placing timber in a running stream for a time before stacking helps seasoning and renders it less liable to decay. But it is not always convenient nor is the timber as good as if seasoned other ways, for it carries off more matter than necessary. Some say leave timber in the bulk some time before cutting into planks. There is great danger in doing this, for if there are any cracks through the bark to allow the moisture to lodge in, decay is certain. The best way is to cut the timber into planks at once after felling, and place it in a store or shed with good ventilation, but no violent draughts of air and no moisture. The floor should be perfectly dry and the roof lofty. In stacking the timber it is well, when convenient, to stand the planks on end, the root end upward, and well raised from the ground. In all cases, each plank or board should be separated from the next one by laths, to allow the air to circulate freely between them. After being in this position for four or five months it is well to reverse them, and brush off with a hard brush any moisture or mildew that may appear. Timber seasoned in this manner proves the toughest and most durable. In seasoning, hardwoods take about one year to the inch, and soft woods much less. Where it is possible, it is well to cut all timber into scantlings, and in panels or boards to plane them some time before being used, as they are apt to shrink, no matter how long they are seasoning, for the wood which requires least seasoning is generally found to be the most durable; it then becomes an essential point that trees should be felled during the winter months, that being the season when the tree has least sap or vegetation within it.

No. 808. SATURDAY, May 14, 1887. Vol. XXXI.

"This is an Art
Which does mend Nature: change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

ROSE GARDEN.

T. W. GIRDLESTONE.

THE HARDINESS OF TEA ROSES.

THE experience of the past winter affords valuable evidence of the fact, now happily becoming generally realised, that the Tea-scented Roses are not too tender to be successfully cultivated out of doors in spite of really severe weather, and if the suggestion that they are hardier as a class than the Hybrid Perpetuals cannot be considered as proved, yet there is no doubt that the tenderer Hybrid Perpetuals suffer far more during a severe winter than do the hardiest of the Tea-scented varieties. By the last are not meant *Gloire de Dijon* and its giant progeny, nor yet the varieties which betray so strong a Bourbon influence as almost to forfeit the right to be considered Teas at all, and of which *Sombreuil* might be instanced as a type, but varieties like *Caroline Kuster*, *Jean Ducher*, and *Madame Lambard*, which, in spite of the low temperatures to which they have been exposed, are in far less sorry plight than such neighbours as *Madame Prosper Laugier*, *Marie Finger*, or *Lady Sheffield*.

A fairly conclusive test was applied this winter to a considerable piece of Teas, including several hundred plants of the best varieties on Brier seedling and cutting stocks, planted on somewhat strong ground absolutely unsheltered, being exposed to every wintry blast. These plants were left without artificial protection of any kind, having neither Bracken among their tops nor a mulching upon the surface of the bed. When the thermometer, suspended on the side of a wooden shed at a height of some 4 feet from the ground, registered 7° Fahr. on two successive nights, grave fears were entertained that there might be a piece of spare ground for Peas or early Broccoli when the *débris* should have been cleared away, but now that pruning time has come and gone, the only variety of which plants are found to have been killed outright is *Madame Bravy*, and even that is not wholly annihilated; while such sorts as *Comtesse de Naudaille*, *Souvenir d'Elise Vardon*, *Niphotos*, &c., commonly regarded as so tender, hardly show a gap in the row.

It was further observed that there was no perceptible difference in the condition of these exposed plants and those which had been carefully protected with an abundance of Fern, and some people have consequently been disposed to raise the question of the utility of the proceeding of wrapping Teas up in Bracken during winter, on the ground that it is unnecessary if the weather be mild; whereas if the frost be severe, Fern appears inefficient.

Without pronouncing definitely for or against Fern as a winter protector, in the absence of more copious evidence, there is little doubt that Tea Roses may be far better preserved from harm in winter by being earthed up than by any other means. Of all the plants in the open those are now in much the best condition which in early winter had the soil drawn up round them about 6 inches high, as if they had been rows of Potatoes. In no case was the wood killed below the level of the top of the drawn-

up soil, although this was frozen solid for considerable periods during the winter, and, in addition to being apparently more effective, the plan of earthing up is infinitely preferable to covering with Fern for protection, from the gardener's point of view. For while in the latter process the beds get trampled down hard, and a considerable litter is involved both when putting on and removing the Fern, not to mention the effects of wind throughout the winter, by means of earthing-up the plants the surface of the beds is kept open, there is no untidy litter, and the ground is thoroughly cleaned by the process both in autumn and at the time of levelling down again in spring. Tea Roses will always have the reputation with some people of being tender, on account of the amount of dead wood that frequently has to be cut out in spring; but it should be borne in mind the Teas will nearly always go on growing in late autumn until interrupted by actual frosts, and that consequently there must be a number of green pithy growths which are naturally destroyed by a cold winter. The thoroughly ripened wood, however, will survive exposure to really low temperatures, and even where the Teas seem more seriously cut back than the Hybrid Perpetuals after the winter, the recuperative power of the former is such that they will probably recover and make far finer plants again by autumn than the latter. For the vital energy of the Tea-scented Roses is such, that they are liable to go on growing continuously unless the needful period of rest is summarily enforced, so that a winter of some severity is a decided advantage so long as it does not quite annihilate the plants, and to do this its severity must evidently be considerable.

A good Rose.—It has so long been thought there is no variety so generally useful and popular as the *Gloire de Dijon*, that we are apt to become sceptical as to the probability of its being ever supplanted, yet this seems likely to happen. This formidable rival will be found, I firmly believe, in *Bouquet d'Or*. I recently saw several strong plants growing in a large Rose house near Bath. They were trained up the rafters, strong bushes of other Teas being grown underneath. At first sight I thought it was *Gloire de Dijon* and commented on it as such, but was assured by the disinterested grower that it is really superior to that variety. It apparently possesses all the good qualities of the *Gloire de Dijon*, and in addition gives far better formed blooms. The one great fault of the *Gloire de Dijon* is its habit of producing so many blooms with ugly twisted centres, and as *Bouquet d'Or* rises superior to this weakness, it may safely be termed the better of the two.—W. L.

Marechal Niel Rose failing.—It is pretty well known that this Rose is liable to canker, and it is very annoying to see strong, handsome Rose trees canker in various parts, causing their rapid decay and ultimate death. There is now growing in the nurseries of Messrs. Paul and Son, Cheshunt, a magnificent specimen of this Rose in perfect health, and it is about twenty years old. There is something remarkable about it besides its vigorous development. The bark has all been scored and cut through to the wood with a sharp knife. Mr. Paul says this prevents canker, by allowing the crude sap to escape at certain seasons of the year. The large Rose tree in question is growing under glass trained to the roof. Its flowering period is April or May, and when the blossoms are all removed the young wood is cut back again; it is summer-pruned, and this is the time to run the point of a sharp knife down the bark or across the old branches longitudinally. The knife is very freely used indeed. This is a very simple remedy, or what is better, a preventive. Probably, if canker once set in, the scoring process might not be so effectual. Mildew is very troublesome on this Rose, and if this parasite or greenfly should spread very much over the

leaves, the growth is checked and canker ensues, or, what is much the same, some of the branches die off. Nearly all the ills which plant life is heir to are caused by allowing insect pests and parasites of various kinds to subsist upon the leaves. We had a house at Loxford Hall in which were two trees planted out. They did well for three or four years, but one of them cankered and ultimately died. The other did very well, except that it felt the influence of London fogs; the leaves would drop off before their time, but we struggled on with it and obtained an annual crop of pretty fair blooms, not like those exhibited at South Kensington by Mr. Walker the other day, but probably as much valued, as they were the best possible under unfavourable circumstances.—J. DOUGLAS.

THE PRUNING OF MARECHAL NIEL ROSE.

"V. M. Devon" (p. 411), states his case so clearly, that he deserves a prompt answer. His case is also so truly typical, as to deserve careful and full consideration. His Rose is so good and so full of wood and of bloom, and yet the plant produces more shoots at the best possible place, too many, indeed, for its present health and permanent vigour and stability. It is simply a case of too much of a good vital force and growing vigour outrunning available area. The question narrows itself, therefore, to this, the striking of a nice balance between the old wood and the new, so as to gain the highest results in vigour and stability of plant and prodigality of bloom.

As to the first two, there can hardly be a question that the best course probably is to cut out one or several of the older shoots that have already bloomed, and lay in some of the young ones to take their place. This plan of leading up growing shoots of the *Marechal* from the base is the surest antidote to warts and exhaustion, as it thus virtually renews its growth and extends the area of its roots and tops every year.

The effects on the amount and quality of the blooms are also obvious. As far as mere numbers are concerned, possibly the close spurring of the old wood would have the advantage; but were the flowers weighed, the young wood would win in a canter. One must see and handle the flowers from young wood to appreciate the enormous difference in texture and size between them and those from spurs on older wood. But the best mode for such fine *Marechal Niels* as the plant your Devon correspondent is favoured with is to adopt the mixed system of spur and long-rod training and pruning. So long as the plant continues to break near its base, lay in one or several shoots annually, and cut out so many older ones to make room for the new. By this simple process, the largest possible number of blossoms from a given area may be gathered, and the plant will probably remain in robust health if properly fed with top-dressings of manure water, &c., while it retains the force of thus renewing itself from near the root-stock. D. T. F.

Manure for Roses.—Some remarkable specimens of Roses in pots are to be seen at the Royal Nursery, Slough—remarkable not so much from their size, for they are young plants of medium dimensions, as from their wonderful development of foliage and the number and size of their buds. This is attributed to the use of Jensen's fish manure. Mr. H. Turner states that as soon as the buds began to appear a good surface dressing was given, and the virtue in it is carried down to the roots when water is given to the plants. The effect of this manure is really surprising, and so a wrinkle is afforded for such rosarians as grow Roses in pots. The Slough Roses should create a sensation at the Royal Botanic Society's exhibition on May 18.—R. D.

Naming Roses.—May I venture, as a Rose-grower, to join in Mr. Girdlestone's appeal in your issue of 30th of April as regards the naming of new (and some old) Roses. I wish that some international society could be formed which would grant certificates only for real novelties or sports perfectly distinct, and no sport to have a certificate

unless it had been proved by the committee for three years; moreover, to refuse certificates to any Rose (however good) whose name contained more than two words. As regards the naming of new French Roses, I hope the new French Rose Society (if ever formed) will do its best to put a stop to these fearful jaw-breaking names. As Mr. Girdlestone rightly says, the south of France rosarians are the worst offenders, but around Paris there are a few who are not innocent. I think that English, and perhaps more especially American, rosarians can pride themselves on the shortness of the names they give to their novelties.—A ROSE-GROWER IN FRANCE.

SHORT NOTE. ROSES.

Rose Marechal Niel.—It would be interesting if correspondents would note carefully this season the condition, after the recent severe winter, of Marechal Niel on various aspects. It has been noticed that of a considerable number of plants in different positions, those facing north appear far less injured than those having any other exposure, and at the present time the former are forwarder and breaking more strongly than the latter. On the other hand, the plants facing south-east were the most severely damaged.

EDITOR'S TABLE.

WOOD FORGET-ME-NOT.—The Swiss Forget-me-not and other kinds have become so popular of late, that the Wood Forget-me-not is scarcely grown enough. It is pretty in woody and bushy places in spring. A good white and the usual blue variety are pretty in a bowl in a cool window.

*

SOME WOOD TULIPS (*T. sylvestris*) FROM THE MEADOWS.—I planted many sent to me by Edouard André from Touraine. The chain-harrow and the roller far from beneficial to the foliage; would have been better in a copse or bushy corner.

*

HORSFIELD'S NARCISSUS, cut in the bud state still good, though cut for nearly three weeks.

*

SNAKE'S-HEAD.—This graceful flower is so modest in the Grass, that it is as well to bring it nearer to one in the room—both the white and common forms.

*

SPRING STAR FLOWER (*Triteleia*).—This I have tried in Grass, and it seems so far to be very happy, and looks very pretty and distinct. Pretty in the house, too, but the strong Onion odour of the stems makes it unpleasant to gather.

*

COWSLIPS, gathered leaves and all—or indeed in any way—fine in a bowl to themselves, and consoling to those who do not buy Orchids at two hundred guineas a plant.

*

THE WHITE CREEPING FORGET-ME-NOT (*Omphalodes verna alba*).—I enclose flowers of this pretty white Forget-me-not. This is a plant but seldom met with in gardens. I have it growing freely in the open border on a light gravelly soil; it is of a creeping habit and perfectly hardy. It looks very pretty planted alternately with the blue *Omphalodes verna* or *Lucilia* in the front of the shrubbery border.—T. B. FIELD.

*

PRIMROSES.—Various friends send beautiful forms of the Primrose and Polyanthus, and so swell the great mass of evidence that we have already of the beauty in all ways, and the rich variation, of our native Primrose, which in its wild form is certainly as beautiful as anything raised from it. The woods in Sussex now are more beautiful than any garden, carpeted with

bosses of Primroses, Lady's Smocks, and Violets, from which rise the beautifully-coloured stems of the Oak in all directions. It is a glorious garden and a lovely picture in one. Mrs. Maxwell's Polyanthus from Kirkeconnell, Newabbey, are very beautiful, and this is the description we must give to all. Mr. Beachey, Kingskerswell, also sends a beautiful box, and says:—

I forward you a box of Primrose and Polyanthus blooms, all seedlings, raised by me here, the result of many years' careful selection. I have attached names to only a few. I believe that you will find all worthy of a careful looking through. Specially would I draw your attention to those in-hose Victoria a this year's seedling, which is, I should imagine, far and away ahead of anything of the sort ever raised before. Prince of Orange and others you will recognise without names, and others for brilliancy of colour and shape, combined with size and other qualities, I am told by experts, who have seen them, are quite unique.

What is worth naming or unique it is extremely difficult to say for one who has seen good collections such as Mr. Waterer's and others that we know. Many lovely things are raised, and probably in the end it is found that if great care is taken in raising seed from good races the best way will be to throw them into groups of colour and to propagate from seed; increasing them by division is a slow process, and the named kinds do not continue to be so pretty and interesting as they are at their first appearance. Mr. Job Candwell, of Wantage, seems to send them from Berkshire as fresh as they come from any other county. He is rather rich in what he calls galligaskin Primroses, and sends them tastefully packed in bunches of their own beautiful leaves. Even in their monstrosities they have a wonderful charm of colour.

*

PRIMULA ORCONICA.—Mr. George Bolas, of Hopton, North Derbyshire, sends us a bunch of *Primula obconica*, fresh, with the following:—

I fully endorse all said about this *Primula* last week, but should like to add another good property to its many. The enclosed flowers were cut three weeks last Monday, the water being replenished now and again.

*

THE WILD PANSY.—The same gentleman sends a very welcome little flower, the yellow wild Pansy (*Viola lutea*), which to me is as pretty as anything in its wonderful grace. He speaks of it as covering, with its blue companion, the hills in North Derbyshire in wonderful profusion. The little bunch of cut flowers is very pretty. Mr. Bolas also sends a good form of the Wood Forget-me-not, which comes quite fresh.

*

THE ORANGE DIPLACUS (*D. glutinosus*).—Mr. Bolas sends this, and praises it very much as a fine old plant and excellent for cutting. We have always known it as a neglected plant. His form of it is very fine in colour—a true flame colour.

*

SALVIA VIOLACEA.—A bunch of this with its purple bracts also comes from Derbyshire with the following note:—

It makes a pretty contrast through the winter and spring for conservatory work, mixed with the Apple-scened *Salvia*; both varieties best pot-bound to induce free-flowering plants. It also makes a telling mass outside. All visitors here generally go up to it and make inquiries about it.

*

AMERICAN COWSLIPS.—The first flowers of these from North Derbyshire. A delicate, bright crimson-coloured form. A pretty plant, of which we never see nearly enough.

*

DOUBLE SCARLET CROWN ANEMONE.—Mr. Prior, of Bury St. Edmunds, kindly sends a bunch of a beautiful double scarlet Crown Anemone, a brilliant and useful thing in a cut state,

looking extremely well for a considerable time in certain positions in rooms. He says—

It is quite hardy; not even sharp frosts affect it. At the present time I have several hundreds of flowers, and from the middle of April it has been one mass of scarlet flowers.

*

CRIMSON VELVETY DOUBLE PRIMROSES.—A pretty bunch from Mr. Hartland, of Cork, who says—

It is a pity so many persons complain of the delicacy of this beautiful variety. I find it quite easy of cultivation, delighting in a rich yellow, turfy loam, mixed with some leaf-mould and coarse silver sand, and planted on a bank against a wall with a northern aspect. Here it grows in great profusion. The bank extends somewhat about 200 yards, 5 feet wide, sloping from 4 feet high at back to 1½ feet in front, and we have no trouble under such conditions with all our rare Primroses and Oxlips, *Primula rosea* and *myalis*, including the much talked of *Primula auricula lutea* and its larger golden form, the true Dusty Miller. I send you some blooms of the Pompadour Primrose, also foliage, for editor's notes. What a scarce plant *Primula elctor eerulea* has become! I find it to grow and succeed admirably on the bank above-mentioned, but impossible to keep up supply, all the celebrated raisers of new Primroses and Polyanthus wanting plants for sake of pollen. There seems a rage now for scarlet Daffodils and blue Primulas. Mr. Max Leichtlin says we are certainly to get the former; we must also get a white *Narcissus cyclamineus* and a white Trumpet Daffodil the size of Emperor. Am glad you liked the consignment of Oxlips sent last week, particularly the giant form William of Orange. This will not give the fasciated stems in the northern position equal to what is got on the plant in a westerly aspect.

*

YELLOW BANKSIAN ROSE.—It is rather early to get this pretty Rose, but Mr. Hartland, who seems to hunt up all sorts of interesting things, should turn his attention to the single Banksian Rose, which we have not had the pleasure of seeing for a good many years. These Banksians deserve attention for their earliness as well as their other charms.

*

SIEBOLD'S PRIMROSE.—Two forms of the beautiful Siebold's Primrose from Mr. Hartland, one delicately fringed. It is much to be wished that our gardeners would learn how to grow them well in the open air. I believe they are very hardy, but it is surprising how seldom one sees them well done.

*

LEUCOCYJUM TRICHOPHYLLUM OR ACIS TRICHOPHYLLUM.—I forward a bloom of this pretty plant. It has, I believe, been lost to our gardens for many years. The only specimen I ever met with was in the Botanic Gardens at Cambridge nearly twenty years ago. It is well represented in the *Botanical Register*, vol. vii., pl. 544, and is there stated to have been received from Lisbon, but in a subsequent note a correction is added to the effect that it came from Moscow, and was probably a native of one of the southern provinces of Russia. Acting upon this supposition, Mr. Lynch very kindly made inquiries on my behalf, but found that it was unknown in Russia. Since that my friend Mr. Wolley Dod, and also Mr. Barr, have obtained and given me bulbs from Portugal, and the enclosed is my first flower.—T. H. ARCHER-HIND, *South Devon*.

*

WHITE WOOD HYACINTH.—Messrs. Veitch, of Exeter, send a beautiful creamy white Wood Hyacinth, which they call *spicata*, but which, no doubt, is a well-grown form of our Wood Hyacinth. The white and coloured varieties of this flower deserve the best attention of all who care for hardy flowers. They come in so well with the common one, and look so well either indoors or out.

*

THE HOOP-PETTICOAT NARCISSUS comes (very good) from Messrs. Veitch, and in the climate of Exeter no doubt it is happy, and grows more vigorously than about London. They also send the Primrose Polyanthus. This is a simple sul-

plum-coloured Primrose, with the stems raised, like those that we call the Bunch Primroses.

*

HOSE-IN-HOSE AND JACK-IN-THE-GREEN POLY-ANTHRUSES.—Mr. Horley, of Toddington, Beds, sends me these, of which he says—

I have a bed of these seedlings upwards of 20 yards in length and 200 plants in number, all at this time being a mass of bloom.

But however curious, we think they are not beautiful, and the cultivation of monstrous developments requires to be checked.

FERNS.

W. H. GOWER.

HUMATAS.

THESE are dwarf creeping plants, with scaly rhizomes, somewhat resembling the Hare's-foot Ferns, and by some authors are included with the Davallias. The genus comprises about a dozen species, several of which are still desiderata in our collections. They all require the temperature of a stove, and all form exceedingly handsome objects if fixed on old stumps of wood or stems of Tree Ferns, as their creeping root stocks readily cling to such a surface, and their fronds will speedily clothe them with beautiful verdure. It is not necessary for the stems to be dealt on which Humatas are planted, for as they are of a dwarf habit, they produce a nice effect when affixed to the stems of growing Tree Ferns.

H. HETEROPHYLLA produces fronds of two forms; the infertile ones are simple, somewhat ovate-lanceolate in outline, about 6 inches in length and 1 inch in breadth; the fertile ones are much narrower and deeply sinuate, and bright shining green in colour. It is found wild in Singapore, Penang, and several of the Malay Islands.

H. ANGUSTIFOLIA is perhaps the least ornamental species of the family, but it is very distinct, and forms a pleasing contrast when grown with other Ferns having finely-divided leaves. The fronds are simple, linear, from 6 inches to 8 inches high, and much less than an inch wide. It comes from the Malay Islands.

H. PEDATA.—This is a very handsome kind, producing stout coriaceous fronds, which are deltoid in outline and about 8 inches high, the upper portion being once divided (pinnate or pinnatifid), the lower pair of pinnae being again somewhat deeply lobed. The sori, which are produced in great profusion, are situated near the margins and are very conspicuous, and add materially to its effect. The colour is deep green on the upper side, but paler beneath. It is found in Sikkim and the Neilgherry Hills, at from 3000 feet to 4000 feet elevation; it also occurs in the Malayan Islands.

H. ALPINA is a small, but remarkably handsome plant. It resembles the preceding in miniature, but its fronds are both smaller and more finely divided, triangular in outline, and deep green. It is found in Borneo, Java, and several of the Polynesian Islands.

H. TYERMANI.—Some doubt is attached to the origin of this species. On its first appearance in this country it was said to have been introduced from the west coast of Africa. Soon afterwards it appeared in another garden in quite a different part of the country, and here it was stated to have originated from amongst some *Dendrobium nobile* imported from Northern India. It is a very distinct and handsome plant. The rhizome is stout, densely clothed with large white chaffy scales; the fronds are triangular, from 6 inches to 9 inches

long, coriaceous in texture, and very deep green in colour above, greyish green beneath.

Other distinct and handsome kinds of Humatas are *H. vestita*, *pectinata*, *parallela*, and *sessilifolia*.

OUR NATIVE FERNS.

MANY British Ferns are very variable in character, and such kinds as the Lady Fern (*Athyrium Filix-femina*), the Male Fern (*Lastrea Filix-mas*), and the Hart's-tongue (*Scolopendrium vulgare*), of which last named species a correspondent some four years ago sent us a printed list of over 130 named varieties, produce so many sports or seedling variations, that the description of all those already known, besides being tedious and uninteresting work, would be an almost impossible task, for some of them resemble each other so closely, that no amount of careful and accurate description could fairly enable anyone to identify them without having recourse to the only satisfactory process, viz. comparison. I will therefore strictly confine my remarks to the most striking varieties, and in order to make the rambles of my readers through woods and lanes more attractive, point out the various places where the original species are found growing in a natural state. The habitats of British Ferns are so various, that it would be a perfect waste of time to look for certain kinds, such as the Royal Fern (*Osmunda regalis*), or the Hart's-tongue in naturally dry situations; and nothing short of failure could be anticipated by anyone looking for such as the Wall Rue Spleenwort (*Asplenium Ruta-muraria*) or the Scaly Ceterach (*Ceterach officinarum*) in continually wet places. Some species, however, are not so particular as to their natural position, and are found growing equally well by the roadside, under hedges, in moist meadows, under thickly-clothed trees, or fully exposed to sunlight. These are principally strong-growing kinds, such as the Lady and Male Ferns, the black Spleenwort (*Asplenium Adiantum-nigrum*), the hard Fern (*Blachnum Spicatum*), the common Bracken (*Pteris aquilina*), and the soft and prickly Shield Ferns (*Polystichum angulare* and *aculeatum*). The differences in their constitution render different modes of culture necessary, and it is because all our native Ferns are subjected to the same treatment that so much disappointment is experienced by growers who are unacquainted with the requirements of the plants. Such being the case, I will endeavour to point out the conditions most favourable to the growth of certain species as regards soil and situation, and these conditions will be equally applicable to their varieties.

Of all our native Ferns, the genus *Lastrea* is one of the largest, and also one which occurs in most districts, some of its members being found in nearly every part of the three kingdoms. On account of its hardiness and of its easy culture, the Male Fern (*Lastrea Filix-mas*) may with every reason be considered one of the very best either for town or for country treatment, as it stands smoke better than any other British Fern. Besides, it has naturally a noble port, and when planted in naturally sheltered places, it is a very nearly evergreen species, most useful for ornamenting the rockery and the corners in the shrubbery. Like many other Ferns, this looks much more handsome when planted out, especially if disposed upon an irregular surface in masses of six or eight strong plants in a clump, with a few large pieces of rock, which greatly add to their appearance, laid in between and among them. A most striking illustration of the above arrangement is in existence at Ashurst Park, the seat of Mr. G. Field, at Tunbridge Wells, where British Ferns (species and varieties) are grown to perfection. The Male Fern is too common a plant to require a special mention of its native habitats; in fact, the difficulty would rather be to find any wide extended district in which it could not be found. The variations from the type are very numerous, and many of its varieties are exceedingly interesting and beautiful. The Male Fern is not in any way fastidious, and will grow luxuriantly either in pots or planted out in almost any soil, provided that during its growing season it re-

ceives a good supply of water at the roots; but it prefers, however, a light and sandy loam to a stiff clay, and although it will stand a good deal of sun, yet it flourishes much better in a shady situation. It is readily propagated from spores, which are ripe soon after midsummer, and also from division of the crowns, which is a much slower process.

Next in importance in the genus, on account of its decorative qualities as well as for its hardiness, comes the *Lastrea dilatata*, a very vigorous grower, producing when in good condition some really gigantic fronds, more decomposed and much more finely divided than those of the above-named species, and, like it, found wild in so many places that no special locality need be specified. It is an extremely variable Fern, which differs in form and stature in accordance with the situation in which it grows; thus when found in a situation which is wet in the spring and dried up in the summer, as on the margin of a pond, its fronds are very dark, large, and quite drooping. A dry and rocky, or a confined situation renders the fronds small and less divided, the pinnae blunt, deflexed, and drooping; whereas permanent wet will elongate the fronds and separate the pinnae and pinnales. It is a very valuable plant for adorning the rockery, the shrubbery, and the edge of the lake, and though it will grow well when exposed fully to the light it attains a much greater size, and is far more beautiful when grown in the shade. This handsome species, whose fronds frequently attain 4 feet in length, will grow very well upon an elevated position that is shaded, but the situation the most appropriate to its well-being is a somewhat constantly moist spot, where it should be planted in a compost of fibrous loam, sand, and leaf-mould, or peat. When sheltered it retains its fronds through the winter, and is freely increased from spores which ripen about September.

THE NARROW PRICKLY-TOOTHED FERN (*Lastrea spinulosa*) is a species closely related to the one just described, from which, however, when grown together it is entirely different. It is a fine, erect-growing kind, remarkably well adapted for the decoration of the rockery and the shady parts of the shrubbery, and although it will bear a moderate amount of exposure, it attains greater magnitude according to the degree of shade under which it is grown. But whichever situation it may occupy, a good supply of water is indispensable to its roots, as it has been found naturally wild in marshy places, moist wooded ground, and wet hedgerows; at Woolston Moss, in Lancashire; Newchurch Bog, in Cheshire; Titterstone (Clee Hills and Bonere Pool, in Shropshire; on Dallington Heath, near Northampton; at Tunbridge; near Torquay, and in a wood near Dunsford Bridge, in Devon. The equally beautiful, though less known

MOUNTAIN BUCKLER FERN (*Lastrea montana* or *Oreopteris*), though deciduous, is a thoroughly distinct and fine plant for the outdoor fernery. It is of medium growth only, its fronds being erect, spear-shaped in outline, rarely exceeding 2 feet in length, and is particularly adapted for planting in exposed situations. As its name implies, it is usually found upon mountain heaths, but it is also an inhabitant of shady woods where the soil is moist, and has been collected at Old Foot's Well, Bromsgrove, in Worcestershire; near Chapel Wear-dale and Darlington, Durham; in the woods at Castle Howard, in Yorkshire; at Conham and Leigh Woods in Somersetshire; near Wrexham, in Denbighshire; also in several parts of Scotland and Ireland. It is one of the few species which do not take to transplanting very kindly, although, with a little care, it may be successfully removed. In any case, thorough drainage is necessary, and the soil best suited to its cultivation is a compost of two-thirds of fibry peat and one-third of leaf-mould, loam, and silver sand. It is most effective when planted in masses on the rockery.

THE HAY-SCENTED FERN (*Lastrea recurva*, *amula* or *Femiseii*) is a very distinct species, which, through its peculiarly crisped appearance, is readily distinguished from any other of the tribe. Its fronds, more triangular in outline than those of any other *Lastrea*, are of a bright, pale green colour, with the pinnae very much curled, or crisped upwards,

giving the upper surface quite a concave appearance. The stalk curves gracefully downwards, the lower half of it being destitute of pinnae, but thickly clothed with long, narrow, semi-transparent scales of a particularly pale colour. This Fern, of dimensions comparatively small for a *Lastrea*, though occurring sometimes in dryish situations, is usually found in moist, sheltered, woody places, and on the banks beneath the hedges. It is not generally found in the British Islands but is abundant on the western side of England, as Cornwall and Devon; also in Somersetshire, Sussex, and Cumberland; and in Wales, in Anglesea and Glamorganshire, and is found wild in the east and west Highlands of Scotland. It is of very easy cultivation, and may be grown with success in almost any degree of shade, excluded entirely from the sun to a situation exposed to its full rays; but in the latter position it is of less luxuriant habit, whereas it will, in the shade, unfold its fronds abundantly and make a noble object. It is an evergreen species, and sandy loam with a little leaf-mould is the soil which suits it best.

THE MARSH BUCKLER FERN (*Lastrea Thelypteris* or *palustris*) is a plant of peculiar appearance, and entirely distinct from any other species on account of its erect, delicate bright green and usually smooth fronds being produced in abundance from slender, underground, creeping rhizomes, and also on account of their being so irregular, that while the barren fronds seldom exceed 1 foot in length the fertile ones often measure over 2 feet. It is a Fern which by its nature is specially adapted for naturally and permanently damp places, as it is found wild in boggy meadows and marshes, especially where the soil is gravelly, and though found in various parts of the British Islands it is very local. It has been gathered in England near Settle, in Yorkshire; at Allesley, in Warwickshire; on Oxton Bogs, in Nottinghamshire; at Belton and near Bungay, in Suffolk; and in a bog in Waterdown Forest, near Tunbridge Wells. In Wales in a moist dell at the foot of Snowdon, near Llanberis; and at Beaumaris, in Anglesea. In Ireland on the marshes of Glencree, in Wicklow; and at Neveaus, Killarney. The Marsh Buckler Fern forms a very ornamental subject when grown in a shallow pot or pan, as it only requires superficial room, its roots keeping at the surface of the soil, and is at home at the base of a rockery where, when once established, it produces its fertile fronds, which are by far the prettiest, in great abundance. It is a plant which does not bear exposure to the sun, which soon discolours its foliage and gives it a peculiarly brownish tint, when the decaying process soon takes place. A very porous compost in which gravel or coarse sand largely preponderate is necessary to the welfare of this pretty species, which when grown in pots requires a constant and liberal supply of water. It is very readily propagated by division of the roots or rhizomes, which are produced abundantly. There are besides the above-named species the Rigid Buckler Fern (*Lastrea rigida*), which is almost confined to the limestone mountains of the north of England; the *Lastrea remota*, also the *Lastrea cristata*, which for some unknown reason is called the Crested Shield Fern, although it shows not the least signs of being crested. But these are amongst our rarest Ferns and very seldom met with, either in cultivation or in a wild state. All the *Lastreas* are exceedingly useful for early spring decoration where they can with advantage replace some choicer kinds. When used in this way they should remain outside all through the winter, but not be allowed to get dry at the roots, although entirely deprived of their foliage. They should then, by the middle of February, be put in a pit, frame, or house where a little heat is kept, and where in two or three weeks they will have developed a whole crop of foliage, the pale and fresh tint of which forms a most pleasing and agreeable contrast with that of half hardy Ferns, or of the spring flowers with which they may be associated in the conservatory.

S. G.

Gardeners' Orphan Fund.—Will you kindly allow me, through your columns, to urge upon gardeners the need

of filling up and returning by Saturday, the 21st inst., forms relative to the above in order to enable the committee to decide upon future action in this important undertaking.
—GEO. DEAL.

FRUIT GARDEN.

W. COLEMAN.

RED SPIDER IN FRUIT HOUSES.

A DRY, cold winter, succeeded by a keen, harsh spring, with wind blowing principally from the north and east, may well be dreaded by the practical fruit grower, for he knows how quickly incessant firing, accompanied perhaps by dryness at the roots, brings spider and other insects into existence. The past season has been especially favourable to the rapid spread of our worst of all insects—red spider—in vineries, and, unless timely steps are taken, soon we may expect to hear of the most promising crops of Grapes having been marred or spoiled by this insidious little pest. Although it is the smallest of all the insects with which we have to contend, the experienced Grape grower cannot walk through a vinery on a bright day without detecting its presence, and sharp, indeed, must be his action if he succeed in breaking up the first colony before some of his finest leaves are sapped and ruined. Spider is sometimes carried from one house to another not only by plants, but by the attendants, whose duties take them through every compartment many times in the course of the day, and one of my most highly valued friends assures me that it is migratory, as he has frequently seen it travelling along the copings of his vinery walls from old to pastures new. The most common cause of its premature appearance, however, is due to imperfect cleansing in winter; it may be of the bark of the Vines, or it may be of some part of the structure itself. Be this as it may, the most fertile cause of its spread is aridity of the atmosphere from incessant fire heat, imperfect ventilation, and an insufficiency of water to the roots; indeed, the latter defect not unfrequently ensures security of tenure when the most approved remedies for its destruction fail.

Dryness being the cause of its development, it is but reasonable to assume that water is the best agent of destruction; but then it unfortunately happens that incessant syringing soon destroys the bloom and renders Grapes unmarketable if not uneatable. Still, whatever insecticides may be used, water to the roots, water wherever it can be applied, must be accepted as one of the most potent auxiliary agents in its destruction. Soft water, free from lime, is best, and a thorough drenching that will wet every leaf and berry will do less harm than light showers of spray; but, prevention being better than cure, I have always made a practice of putting in a syringe of soft water wherever it can be driven against the foliage without running the risk of wetting a berry. Rather late in the evening is the best time to apply this preventive remedy, and some little practice with a trusty syringe is necessary, but it can, and has been done here for years with the most satisfactory results. When this does not produce the desired effect, and the spider from old spurs fastens on the leaves immediately above the bunches, sponging with soapy water, a decoction of Quassia chips, or Tobacco often nips the enemy; and, last of all, in one or more of its many forms comes sulphur. Sulphur, however, is not always a harmless remedy, as many a house of Vines, by its use or abuse, has been ruined for years in the twinkling of an eye. This remark need not deter careful people from using it, as we frequently hear of mishaps brought about by the injudicious application of some of our oldest and

best-tried insecticides. Sulphur, in the first place, should never be applied to the pipes until after the Grapes have passed the stoning stage, otherwise rust will most likely follow, and then even tender varieties, like the Frontignans and Chasselas Musque, often suffer. In the second place, it should never be applied to brick flues, if such still exist, to iron that has been heated in the fire, or newly slaked lumps of lime, at one time so strongly recommended. It may, however, be applied as a paint or wash to the hot-water pipes after they have been heated to a degree that will render them uncomfortably hot to the hand when placed upon them. To prepare a vinery for the fumes it should be shut up hot and dry, at a temperature ranging from 80° to 90°, the wash being applied after the sun has left the roof, when the ventilators may be kept close throughout the night. They must, however, be opened very early the following morning, and unless the operation is to be repeated, when shading should be resorted to, the walls, floors, and all available foliage should be well syringed, not only to break up the webs, but to produce vapour that will render the fumes harmless to the leaves. If the first painting does not make a clearance, it may be repeated once, or perhaps twice, at intervals of two or three days. Many people paint the pipes first and heat them afterwards; but this is a mistake, as they should be hot enough to vaporise the sulphur the moment it is applied. In vineries subject to annual attacks, gardeners use sulphur in the winter dressing, also with the lime applied to the walls, and not unfrequently distribute it over the stems and leaves with the sulphurator; but the best of all preventives is generous culture, with an abundance of air, water, and atmospheric moisture, and last, but not least, moderate cropping.

Identifying varieties of Apples.—We found growing in a neighbour's orchard a valuable early winter Apple with which we were not familiar. It was large, beautiful, free from blemish, productive, and hardy, and the quality pleased me on account of its crispness, tenderness, and mild, sub-acid, Non-such flavour. My neighbour brought the scions from England, where it had been his favourite, and where it was known as Lord Nelson. I exhibited specimens at our horticultural meetings, where no one recognised it, then sent specimens to Charles Downing, and repeatedly wrote and answered letters regarding its identity. Mr. Downing could not name it, and we concluded that Lord Nelson was a correct name, and by that name I propagated it, grafting scions on a large tree near my office door, and the more I saw of it the better I was pleased with it. Charles Downing had subsequently sent me scions of Blenheim, advising me to propagate it. I did so, and after several years found that Lord Nelson and Blenheim were the same. Last year I attended a horticultural meeting at Titusville, Penn. Among the beautiful Apples shown were many examples by different individuals entered "name wanted," and I was asked to name them. I at first replied that I did not recognise the variety, but on closer examination discovered that they were the Blenheim, but much larger and more brilliantly coloured than as grown at Rochester. They were among the largest and most attractive shown. The exhibitors stated that it was their favourite Apple, and most profitable. Mr. Downing had made a special study of the Blenheim, correcting in his recent edition what he deemed errors in previous reports of its characteristics, indicating how easily we may be misled in identification. I am led to make these remarks by reading Josiah Hoopes's favourable notice of Blenheim. He brings out its hardy qualities prominently, more so than we had claimed, not having learned of its success in severe localities. Blenheim has for us as few faults and as many good qualities as any early winter Apple with which I am familiar.—C. A. GREEN, *Monroe Co., N.Y.*

GRAPE LADY DOWNES SEEDLING.

THIS handsome late Grape, part of a crop of which is well figured in the annexed engraving, is the result of a cross between the Black Morocco and the Sweetwater, and was raised about 1835 by Mr. Foster, gardener to Viscount Downe, Benningborough Hall, York. As may be seen by the engraving, there are about thirty bunches on a space of 10 feet long and 7 feet wide, yet this was the lightest of any of my crops of Grapes, and although of good flavour and colour and kept well till the second week in April, was the least profitable. In some cases I had two bunches to a lateral; several of my latest-keeping varieties were so grown. I firmly believe in starting with fire-heat, giving abundance of air; and to my mind this ventilation,

two certain causes of scald. Often in hot, bright weather the temperature inside will be lower than outside, then the rush of warm air will generate steam, and scald will show itself at once. When fire is used a little air on the top of the house all night, increasing before the sun has much power, will be steps in the right direction. I grow Lady Downes, some with one rod to a Vine, some with two, and some with three rods, all at 3 feet apart. The crop is no heavier on the single-rod system, but is ripe first. At date of writing, Lady Downes (my last house to start is looking well, and great care must be exercised in tying down the laterals, as, being so brittle, they are apt to break off. To prevent this, tie slightly down before attempting to finally fix them in position. If these come into flower at

Grape Lady Downes Seedling. Engraved for THE GARDEN from a photograph sent by Mr. Stephen Castle, West Lynn Vineeries, Norfolk.

judiciously given, is of the utmost importance in the treatment of Lady Downes. Some have not hesitated to tell me plainly that I am wrong, thinking that the fire-heat is wasted. Not so. Fire is required; but do not forget air. Give the laterals plenty of space, keeping sub-laterals well in hand. What is to be aimed at is not a quantity of foliage, but fine large leaves, very liberal feeding, in the form of cow manure, soot, lime, &c., being the groundwork of success.

Many causes are put down to scalding, to which this variety is very liable, but to suppose that the sun shining on the berries is a cause is a mistake, as in every case I found my scalded berries on the side where the sun never touched. Low temperature and defective ventilation are

the same time as Black Hamburgh, I shall use the pollen of the latter. At colouring time I find they like plenty of water. Should by chance the borders get dry, the probabilities are that the berries will crack. Very early thinning is wanted for this variety; those bunches taken almost before setting make the noblest Grapes. Alicante and Lady Downes can be well grown together.

West Lynn.

STEPHEN CASTLE.

Syrring Peach trees when in bloom.—

For the purpose of convincing one of my assistants (having tested the matter to my own satisfaction some years ago) I gave permission to have one of the Peach trees syrring with clear water three or

four times a day while the bloom was setting. The result is that there is about the same number of fruit on the tree as there were last year when the flowers were not syrring. This confirms my previous experience that syrring the flowers for the purpose of making them set better does neither good nor harm. I ought to mention that the tree operated upon occupies a position in an unheated house.— J. C. C.

WELL-KEPT APPLES.

THE remarkable collections of Apples exhibited at South Kensington on the 26th ult. by the Messrs. Cheal and Mr. A. H. Snee showed that at least the problem of how to preserve Apples fresh and sound till the end of April, or even later, is solved, and there remains for others having good Apples but to go and do likewise to have beautiful fruits at this period of the year. These Sussex and Surrey fruits had been not merely kept, but they had been preserved in fine condition; indeed, many of the samples, and those of Mr. Snee especially, seemed as fresh and sound as such fruits usually are in November. The Messrs. Cheal's fruits were larger, and evidently grown on young nursery trees. Mr. Snee's bore the appearance of being from robust orchard trees. In any case the condition of preservation was pretty identical. It was very interesting to note that a collection of fairly good Apples from Maidstone, said to have been kept in a dark room and in a low temperature, often, indeed, below freezing point, was still much less well preserved than were the samples from Crawley and Wallington. It would therefore be useful could we learn how these Apples were so admirably kept. Some of the kinds—Emperor Alexander, Ribston Pippin, Lord Derby, Stirling Castle, Blenheim Orange, Calville Blanche, Cox's Pomona, Gloria Mundi, and many others—exhibited were what are termed early winter kinds, so that the admirable condition of preservation was all the more meritorious. It was suggested that some of this excellent keeping was explained on the ground of the thorough maturing which Apples receive in Sussex and Surrey. That, however, would hardly explain all. Really, were a line drawn across England from London to Gloucester, we should find in all its southern part situation and warmth not less favourable than can be found in Sussex, and Apples produced in all those southern counties should be as capable of preservation, if the well-matured theory be the correct one. Of course, thorough maturation is indispensable, but it is certain that something is due to the time of gathering the fruit, something to care in that work, and selecting sound samples for keeping, and something to nature of store, as to which we all have our opinions, but the experience of Messrs. Cheal and Son and of Mr. A. H. Snee would be very valuable, because these gentlemen have shown us that, in practice as well as in theory, they have the proper kinds of stores. Whilst it has yet to be shown that darkness is an indispensable element in Apple preserving, there can be no question as to the need of an equable temperature, for considerable variations in that seem to be exceedingly deteriorating to the fruit. One point is, which is the most desirable range of temperature, and should it ever fall below freezing point? We may be told that the temperature of an Apple store has often been below freezing point, but that information would be misleading were the fruit protected with thick coverings of straw. I do not think anyone will maintain that exposure to a temperature of 28° can be beneficial to Apples, especially if off repeated. I find a general belief prevailing in favour of an earthen floor; not, of course, damp, but through which the moisture always existent in the earth can freely pass, and thus prevent the air of the store from becoming dry. There is one thing to be said, however, in the matter; we have had a long winter almost always cool, and during which everything has been kept at rest. Potatoes have never in my experience kept better than during the past winter, and without doubt Apples have enjoyed the same non-exciting influences; therefore, preserving Apples has been much less difficult than it was during many preceding

winters. The problem of preserving sound Apples through a long winter being well solved, we ought to be able when we have good crops to store an abundance for late winter and spring use, and thus checkmate to some extent the produce of the American orchards which just now commands our markets.

A. D.

GROWING MELONS ON THE EXTENSION SYSTEM.

NOWHERE else have I tasted the Cashmere Melon so good as at Longleat, and probably it is not grown in twelve other gardens in the country. We were led to believe that it could not be properly fruited under ordinary restricted culture, but this I and others have proved to be erroneous. Although good crops have been taken from the restricted or freely stopped plants, the quality was never so good as in the case of fruit cut from plants grown on the extension system. To have Longleat Perfection—the result of a cross between Meredith's Cashmere and Eastnor Castle—at its best, or, say, to equal in quality those grand fruits shown at the Royal Horticultural Society's show at Liverpool last June, or those which Mr. Pratt, the raiser, has repeatedly exhibited in London, the plants must be allowed plenty of room to ramble. This system, which I shall briefly describe, may not be quite so productive as that generally adopted, but if there are fewer fruits they are certain to be far superior in point of weight and quality. Melons can be made to ripen an extraordinary weight of fruit on a given roof area, but when there are only five or six leaves—and these perhaps infested with red spider—to every fruit, the quality is sure to be very inferior. Before condemning the extension system, as some are ready enough to do, they ought at least to give it a trial, and, unless my experience is at fault, they will find Longleat Perfection, Cashmere, Eastnor Castle, or any other variety considerably improved thereby.

THE EXTENSION SYSTEM simply means giving one plant an amount of roof area usually occupied by at least four plants, the treatment at the roots being proportionably liberal. Hot-beds may be formed in the usual way, these being, perhaps, most needed in the early part of the year, about a bushel of good clayey loam and a sprinkling of lime being sufficient for each mound; or they may be grown, as at Longleat, exclusively in pits of soil disposed over bottom-heat pipes. We have tried both plans, are doing so again, in fact, and find our best-flavoured fruits were obtained from plants the roots of which had no access to hot-bed material of any kind. These pits are formed with loose bricks, a thickness of $\frac{1}{2}$ inches being quite strong enough for our purpose, or at the outset they may be four bricks square, and from six to eight bricks deep. They may be filled with the clayey loam and lime, and either allowed to gradually get warmed through, or the whole mass may be quickly warmed with hot bricks buried among it, the latter course being advisable when the plants are liable to become root-bound if left any longer in the pots. Melons generally require to be planted rather high and firmly. If the collar is on a level, or, worse still, sunk below the level of the surrounding soil, they are liable to eanker or rot off suddenly, and the aim, therefore, should be to keep them rather high and dry. At the present time our most promising plants, or those from which we hope to cut good fruit during May, are now showing their topmost roots near the stems, these being stout and green. The soil being well rammed about the roots ensures its being closely occupied by fibre, and this causes a sturdy and fruitful growth. Planted loosely, or even in a more rich soil, Melons are apt to grow as rankly as Cucumbers, but such growth is neither fruitful nor lasting. When first surrounded by this mass of soil the plants require rather careful watering, but by the time the roots have reached the bricks plenty of water must be given, especially in clear, hot weather, and when the fruits are swelling off, water will frequently be needed twice in one day. Plenty of head room being given each plant, three being allowed to fill a house, say 21 feet by 12 feet, a shift must be given, or, in

other words, the pits must be taken down and enlarged a width of two or more bricks. This admits of a quantity of fresh, previously warmed soil being firmly packed around the now partially exhausted heap, and into this the roots quickly find their way, a thin top-dressing also further assisting the plants. Pulverised night soil, mixed with fresh loam and applied as a top-dressing, has been found most beneficial, no other manure being required. Diluted farmyard liquid manure is the next best thing, and at different times we have used Jensen's fish-bone manure and Thomson's and Beeson's manures with good effect. Large quantities of manure are not wanted at any time; they may easily prove harmful unless carefully applied, and a little and often are our instructions to those in charge. If the Melons are planted over slight hotbeds, this being the case with our earliest and successional batches, we still contrive to make use of the loose brick walls. Providing a good level bottom can be found, such as the permanent walls of the pits, a continuation of these with loose bricks enclosing a good quantity of soil, much simplifies the process of watering, and preserves all the outside roots. In very many cases there are only small ridges of soil for the plants to root in, and as it is almost impossible to keep them alive in this, the bulk of the food has to be gleaned from the decaying hotbed material underneath. No wonder that many plants die prematurely, or that fruit ripened on the remainder are of inferior quality.

Training the top growth of unrestricted plants differs materially from that necessary with those thickly grown. They may be either trained straight up the roof and the laterals laid in thinly right and left and not stopped till they nearly meet each other, or the points of the plants may be taken out soon after the trellis is reached, and from four to six growths that follow this stopping be laid in, fan fashion. What is wanted is to gradually and thinly cover the roof with leading growths, abundance of fruit being obtained from the laterals formed by these, stopping at the second or third joint beyond the embryo fruit. It is not the quickest way of fruiting Melons, no attempt being made to secure fruit from the first break or laterals, the sub-laterals being waited for, but by this time the plants will have become very strong, and no difficulty ought to be experienced in effecting a good set at various times. It is no uncommon occurrence to see fruit hanging on one plant in nearly all stages of growth or varying from those ripening to some near the size of Walnuts. Not only is a good succession of fruit thus obtained, but active, healthy growth being maintained, such fruit will be found to be of first-class quality. At Longleat three plants completely cover the roof of a good-sized lean-to house originally built for Vines, and the plants, whenever I have seen them, always appear to be very strong and healthy in spite of the heavy crops being perfected on them. They are well attended to and never allowed to suffer for want of water or fertilisers. Those who cannot devote sufficient time to this method of Melon culture ought not to attempt it, nor should those varieties not possessing a strong constitution be grown where it is impossible to maintain a high temperature at all times. When the temperatures often fall below 70° by night or day, canker and other evils soon set in. Melons require very little air at any time, but should have plenty of moisture about the house, accompanied by overhead syringings in dry, hot weather, both being discontinued should the opposite prevail; no drying off at the roots at any time, though when rather close stopping is resorted to they certainly require much less water when the fruits are ripening.

MELONS CRACKING.—Several who grew Longleat Perfection last season complained of the proneness of the fruit to crack or split badly just before they were ripe, and we discovered the same fault. The only remedy is to maintain a rather drier atmosphere and to cut the fruit before they are fully coloured. If laid on a dry shelf in the same or other house where a high temperature is maintained, what apparently are quite green fruit will ripen beautifully in a few days, and I believe early cutting is the only method of saving the fruit on restricted plants.

Since writing the foregoing I have had an opportunity of seeing the Melons at Longleat. In one house three plants of Longleat Perfection nearly cover a roof area of about 30 feet by 8 feet, and these are now carrying not less than one hundred fruit of all sizes, and more will yet be set. I find they set their first fruit as soon as they can, even if they form on the principal growths. The earliest will be ripe in a few days, and altogether it will be a grand crop.

W. IGGULDEN.

GRAPES MRS. PEARSON AND GOLDEN QUEEN.

Now that Mrs. Pearson is found to possess another good quality, viz., that of long keeping, it will most probably be reinstated in numerous vineries from which it has been elbowed out by more showy varieties. We have two good Vines of it, and this season, but for the timely notice that Mrs. Pearson is really a better keeper than the Muscat of Alexandria, the latter would have been marched on to it. Although not a very vigorous grower, the former requires plenty of room, as it neither sets nor colours well under a heavy canopy of foliage. What it requires is plenty of light, and not full exposure to the sunshine, the former developing the beautiful amber colour. Full sunshine discolours it, while a heavy shade causes the berries, or the greater portion of them, to assume a dirty green colour. It also requires plenty of time and heat to bring it to perfection. Alongside of an equally well-grown Muscat it cuts a rather poor figure, but if others besides Mr. Coleman are as successful in keeping it till March, we may safely predict a greater demand for it.

Golden Queen, I am afraid, will never become popular, owing to the difficulty experienced in colouring it. I have tried it in three different gardens with varying success. No variety possesses a better constitution and it is fairly prolific, setting well, while the berries are large and, if given plenty of fire-heat, are very crisp and refreshing, but, as a rule, the colour is a dirty yellow. Mr. Wildsmith is of opinion Mr. Pearson erred greatly in classing it as an early Grape, but he was not so far wrong as at first sight appears. Let Mr. Wildsmith try a pot Vine in a small forcing house with recognised early sorts, and he will find Golden Queen not so far behind after all. I have grown and forced pot Vines of this variety with good success. The bunches were large, the berries even, and coloured beautifully, or equal to the best Muscats grown, while the quality was said by an authority on Grapes to be the best he had yet met with. Were we in a position to recommence forcing pot Vines, or, better still, small planted-out Vines, Golden Queen would be one of the sorts grown, and Mrs. Pince another—this fickle variety also doing surprisingly well under such treatment. Probably Mr. Wildsmith will have observed that Golden Queen is the first to break and the first to flower in a house of mixed late varieties. At any rate such is the case with us, it being fully a week ahead of Mrs. Pearson, Alicante, and even Gros Maroc, but it ripens slowly, unless a high temperature is maintained. However, if Golden Queen is cultivated, one root will usually be found ample, and in many gardens its place might more profitably be occupied by either Mrs. Pearson or Muscat of Alexandria.

W. I.

SHORT NOTES.—FRUIT.

Apples with handsome flowers—In answer to "W. R. R." in THE GARDEN, who asks (p. 400) about an Apple which produces handsome flowers, I should advise him to plant Lincoln Pippin.—W. INGRAM, *Belenos, Grantham.*

A good keeping Apple—Last November I put away a few good specimens of King of the Pippins Apple in a drawer. I have been looking at them to day and find them almost as fresh as they were when gathered. They are crisp and of good flavour, and I do not think that enough is made of this Apple as a keeping variety.—J. MEIN.

Fig trees in the open—Our Fig trees have never been protected in any way, and I have never seen such prospects of a good crop as there are at the present time, not one shoot in twenty being injured by the frost. There are as many as six nice fresh fruits on some of the shoots, and they are already beginning to swell. The trees are planted on south-west and south-east walls, but those on the former are showing the best crop. This may, however, be owing to their being much older. They are planted on

the Grass, and their roots have never been touched since they were planted. The shoots of last year's growth were not nailed to the wall until they were pruned a week ago.—*D. WALKER, The Garden, Devonian, Taunton Wells.*

Strawberry La Grosse Sucree.—I have on several occasions called attention to the good all-round character of this Strawberry for forcing, and now send you a few that you may judge of its merits. These sent are gathered from a batch of 400 plants, and are not specially picked fruit. They average from eight to ten to each plant, and there are very few small fruit among them. I may add that there is not one blind plant in the batch.—*E. BRIBBLE.*

The fruit sent were large and of a fine rich colour.—*Ed.*

SEASONABLE WORK AMONG FRUITS.

VINES.

THE light showers by which the present month has been ushered in having put an end to frosts for the time being and softened the atmosphere, Vines from the earliest to the latest have made rapid strides, and show by the dense colour of their foliage how quickly vegetation under glass responds to genial conditions. So far, although cold, harsh weather has clung to us, we have little to complain of, and, provided the daily routine is kept well in hand, the crops at one time late will not be far behind at the finish. In early houses containing Grapes now colouring, the principal point will be perfect finish, and as this cannot be secured without the assistance of plenty of fresh air, fire-heat must be applied to prevent the temperature from falling too low. It is very easy to run up the temperature to an extent that will cause the berries to sweat or condense moisture, but this treatment soon reduces the bloom; therefore, whilst giving sufficient close heat on fine afternoons to ensure full size of berry, the stewing system must be carefully avoided by re-opening the ventilators in the evening. When jet-black berries suddenly appear amongst green ones perfect colour is pretty certain, but then even a check must be guarded against, as I have seen the most promising process of colouring suddenly arrested by a change from bright warm to cold, sunless days. Vines which have been heavily cropped in previous years, or now for the first time are just slightly overdone, may possibly be carried through by timely attention to a steady circulation of air in a house that will not exceed 80° by day nor fall below 60° at night, the evaporating pans and floors being regularly supplied with warm, diluted liquid, and the stems bathed with pure soft water to keep the sap in motion. When the colouring process is complete and the Grapes begin to ripen it will be necessary to keep the house cooler and somewhat drier, but the floors and mulching must not be allowed to become dry, as early Vines under daily sun-heat and light will carry off moisture that would be fatal to the crop in the autumn. If more water is likely to be needed before the Grapes are cut a moderate supply should be given at once, and well mulched in with short stable manure to prevent evaporation or the surface roots from becoming dry. A keen eye must now be kept on the foliage, for if hitherto free, it is not unlikely that thrips or spider may start from an unguarded or dry corner, and soon work serious mischief upon foliage, which must be kept fresh and healthy through the hottest part of the summer. Tobacco smoke destroys the first, but the second is more persistent; in fact, bug not excluded, it is the most troublesome insect we have to contend with in our fruit houses, and must be dealt with accordingly. Dry sulphur or a sulphur wash smeared over the pipes when heated checks, but does not always annihilate the enemy. Moreover, its presence in vineries has come to be regarded as a slur upon the cultivator who invariably washes down the pipes when he expects a visitor. To save his trouble and molesty, I would suggest the timely sponging of every affected leaf with warm soapy or weak tobacco water, and incessant syringing with pure soft water whenever a single syringe-ful can be put in without casting spray upon the Grapes. If an early attack is made, sponging is the cheapest, quickest, and most effectual mode of destroying spider.

Succession house.—Here the final thinning out of stoneless berries, and perhaps a little more shouldering may be necessary. Where large exhibition

bunches are wanted their size can be greatly increased by looping up the shoulders, but this work should precede thinning, otherwise many of the prominent berries get cut away from the extremities whilst the centres remain crowded. Next to overcropping, bad thinning cannot be too strongly condemned, for no matter how good the Vines may be, the Grapes cannot be good where this is carelessly performed. When this work is finished, inside borders may be well mulched with short horse manure, and, provided they are well drained, heavily watered with water at a temperature of 80°, the stimulating matter contained in the manure will be quite strong enough for the Vines, but the next supply may consist of diluted liquid. When Vines are doing well it is not a good plan to overfeed with powerful stimulants, and yet, with the view to helping the willing horse this is often done to their detriment. A methodical system of pinching, regulating, and tying down must still be observed, otherwise rampant growers, whilst wasting their strength on the production of gross laterals, will become crowded, and so impede the free circulation of air. Once the whole of the roof trellis is covered, leaders may be trained down the back walls, and weak laterals may have free license, as there is nothing like free growth for ensuring a corresponding development of roots.

Muscats.—Where early and late houses are devoted to these, the latter will now be in flower, a condition which will justify a little extra heat with a free circulation of air. At one time it was the practice to keep the house as hot and dry as a lime-kiln, and to regard water or atmospheric moisture as enemies to fertilisation. Modern Muscat growers have reversed this order, and no doubt they are right, as excessive dryness is a tax on the energies of the Vines, and does not facilitate the setting of the fruit. The principal point in securing a good set is brisk root action in warm, well ventilated, and properly moistened borders, supplemented, as a matter of course, by daily fertilisation with Hamburgh or foreign pollen. Another drawback was the false idea of keeping many strings to the bow by leaving all the bunches on the Vines until after the Grapes were set. As few varieties are more floriferous than healthy Muscats, and a profuse blossom is weakening, the bunches on each lateral may safely be reduced to one as soon as the best can be selected, and then there will be an abundance left to choose from. Lady Downes and Gros Colmar require precisely the same treatment as Muscats, especially through the early stages of their growth. When well advanced, and fine summer weather has set in, a lower night temperature in mixed selections is sometimes necessary, but the best quality, and certainly the best keeping properties are secured when these two Vines are grown side by side with well managed Muscats.

Watering.—The latter part of the past winter and the spring having been exceptionally dry, extra attention to this important matter is absolutely necessary. Modern borders from 2 feet to 3 feet in depth, and resting on a foot of drainage, may easily become too dry, especially when a keen north-east wind of some weeks' duration has been carrying off every particle of atmospheric moisture, but thus constructed it is a difficult matter to over-water during the period of growth. Regular supplies—if tepid, so much the better—therefore should be given internally throughout the season of growth, externally until the rain now due has penetrated to their lowest depths. Once properly moistened and well mulched with fresh stable litter, the annual average rainfall of 30 inches should be found sufficient, but the better to ascertain what is going on below, the main drains along the front with shafts rising to the surface should be open to inspection. When from artificial watering the filtered liquid is found flowing freely, all doubt as to the lower roots having been moistened for the time being is set at rest.

Pot Vines.—An early short-jointed growth from pots well filled with roots must be the first consideration, and when this has been secured thorough ripening is sure to follow. Those intended for next year's fruiting will now take liberal supplies of

weak diluted liquid from the tanks, and an occasional top-dressing, to prevent the surface-roots from becoming exposed. If trained like ordinary Vines to trellises about 18 inches from the glass, they will make more equable canes than when grown upright, and having the full benefit of the sun the lower as well as the upper buds will be properly ripened. Stopping must be regulated by the situation and height of the pit or house in which they are to be fruited, and all laterals from the base upwards to the pruning bud must be closely pinched to the first eye. This will plump up the main buds without endangering them, whilst those above may have more freedom to keep the roots in action.

Vines now carrying ripe or ripening fruit must have more air and a lower temperature to ensure the keeping of the Grapes. Water, too, may be more sparingly used, but not to an extent that will jeopardise the roots or foliage, which must be kept fresh and healthy. Madresfield Court and Foster's Seedling, two varieties subject to cracking, should not receive any water after the Grapes are ripe, but drying out can be prevented by burying the pots in a good body of dry, non-conducting tan or leaves. Vines struck from eyes this spring will now be fit for shifting into 8-inch pots or planting out in warm internal borders where this mode of establishing them is in favour. If the pots in which they are now growing have already been raised to the surface of the plunging bed they need not be replunged after the shift, but water must be very moderately supplied until they have taken to the new soil, and the syringe may be vigorously plied on fine mornings and again at closing time to keep up a proper degree of atmospheric moisture. Laterals should be closely pinched and the leaders stopped where they have made about 6 feet of growth.

PEACHES

in early houses will now be swelling and colouring fast, and possibly in a few instances ripening. The temperature here may range from 60° at night with air to 70° or 75° by day with a free circulation. Air is the grand factor, not only in laying on colour, but also in securing flavour, and the better to ensure a constant circulation without producing cutting draughts, gentle fire heat must always be at command. The syringe may still be freely plied, soft water only being used, and shutting up for an hour or two, not too early in the afternoon, will add considerably to the size of the fruit. Shoots that will be cut out as soon as the Peaches are gathered should be pinched, not only to throw size into them, but also to give those intended for next year's fruiting full exposure to light and air. When the time arrives for gathering directions given in last week's paper on the early orchard house should be adhered to. We used to litter our Peach houses with a quantity of fresh, sweet hay to catch falling fruit, but this was given up years ago, as we find the finest flavoured Peaches are those which we detach with the scissors before they reach the dropping stage. In order to prolong the season of the trees they should be well watered with pure water, and heavily mulched with light manure or short straw some little time before the first Peach becomes ripe or even transparent.

Succession houses. The growth in these is unusually rapid, and, aided by plenty of sun and light, the free admission of fresh air favours the formation of firm, short-jointed wood. This must be kept in proper balance by constant attention to thinning, tying down, and pinching out the points of gross shoots which have reached their limit, or threaten the impoverishment of the lower parts of the trees. An even spread of thinly trained shoots that will shade all the old branches, with plenty of room for the full development of every leaf, should be the great aim; but not one single superfluous growth should be allowed to remain, as overcropping is next-of-kin to over-cropping. Thus managed, large trees with every leaf fully exposed to the influence of sun and light, and not more than 18 inches from the glass, will take enormous quantities of water, and the syringe must be vigorously used twice a day. Houses in which Strawberries or other troublesome plants

have not been grown seldom suffer from attacks of spider, but when they do, a thorough drenching with the engine or hose from the outside on a mild afternoon will generally dislodge it. An indifferent hand with the syringe is soon found out, but the man who lays to backwards and forwards not only moves, but wets every leaf on both sides, and by these means prevents the enemy from gaining a footing. If thinning has not been brought to a close, no time should be lost, and the fruit intended for the crop, averaging one to every square foot of foliage, must be raised to the influence of the sun at leisure.

Late houses.—Thinning in this department is no trifling matter, the fruit on every tree having set unusually well. We do not make a practice of leaving a large percentage to compensate for dropping, especially in late houses, as properly fertilised Peaches always swell away kindly, and unless something is wrong with the roots or in the internal management, timely thinning is an important stepping-stone to full size and good quality. It does not often happen that external borders require heavy watering early in the spring; this, however, has been an exceptionally dry season, and although they have been repeatedly hosed and well mulched, twelve hours' steady rain would quickly be felt by the trees. When the trees in late houses and cases have been disbudded, they should be well syringed and shut up pretty early on fine afternoons to give them a good start, but night air should always be admitted, and ventilation through the day must be regulated by the period at which the fruit is wanted for use. If as late as possible, we ventilate and shut up through May, and throw the house open after the beginning of June. W. C.

STOVE AND GREENHOUSE.

T. BAINES.

CONCENTRATED MANURE FOR POT PLANTS.

In the cultivation of plants of any kind, it is generally admitted that the best time to give manure is from the time their growth begins and onwards. The season is now at hand when most plants are more or less in an active state; consequently, a few words on the subject of manurial assistance may not be out of place. In the case of quick-growing plants, such as Pelargoniums, Fuchsias, Bouvardias, and various others, that admit of the old soil being shaken away and replaced with new at the time the annual potting is carried out, there is little difficulty in giving them much of the manure they require by mixing it with the material in which they are potted. Yet, even with plants of the character named, if justice is done to them, they need further assistance later on in the season in addition to the manure given at the time of potting, as if enough was then mixed with the soil to last until their growth and flowering were finished, it would cause them to produce rank, over-luxuriant shoots at the commencement of the season. Hence, where high cultivation is attempted, manure water or surface-dressings of some concentrated manure are applied to supplement that which is mixed with the soil. With hard-wooded plants the case is different. Being much slower growers than the kinds previously mentioned and others of a like nature, they require proportionately less manure to sustain them, the material—loam or peat—in which they are potted generally containing enough to support their growth for a time without any manure being used with it; but in time it becomes so far exhausted, that it will not keep up the requisite growth; and as few of the hard-wooded plants in question will bear being shaken out of the old soil, it becomes necessary to help them with manure in some shape. An impression used to prevail among many growers of hard-wooded plants,

such as the New Holland and Cape species, including Heaths, that they would not bear anything in the shape of manure; consequently, none was given them, the result of which was to be seen in the starved, stunted appearance the plants usually had when they got old, making little growth and producing few flowers. On examining plants that were in this state the soil in the pots was generally found to be densely packed with healthy roots, whilst the top growth, so far as it went, was equally healthy, the unsatisfactory condition being simply the result of the soil having become exhausted. In cases of this kind, one way of meeting the difficulty would be to give larger pots; but there is a limit to the size of pots which it is expedient to use, both as regards appearance and convenience. Exceptionally large pots are objectionable to look at, and the plants grown in them are cumbersome to move about. With hard-wooded plants that are required for ordinary purposes there is no necessity to use pots that are inconveniently large, as when the plants have been treated liberally in the matter of root room during the early years of their existence and onwards until they have attained fair specimen size, they may be kept for many years in a vigorous, healthy state in the same soil by regular assistance with manure in some form through the growing season. When plants exist under the conditions described, the soil in which their roots are located, having parted with all the fertilising elements which it originally contained, simply acts as a medium through which the roots can be supported with whatever is given them. It thus becomes clear that there must be no break in the supply by giving it in fits and starts in a haphazard kind of way. Each spring, as soon as the growth begins to move, the use of the stimulants must begin and be continued until the wood and leaf extension ceases. After this period the plants are better without any stimulants, as all that is then required is solidification of the shoots, which is effected by light and air acting on the growth that has already attained its wanted size; the comparatively little that is required afterwards in the way of sustenance will be present in the unexhausted elements of the manure given earlier in the season. The principal thing to keep in view when plants are kept for years without change or addition to the soil, and from which consequently the roots have extracted everything in the shape of nutriment which it originally contained, is to provide them all through the time they are making growth with the manure indispensable to maintain the requisite vigour.

In times past when the idea was prevalent that fine-rooted, hard-wooded plants would not bear stimulants, many who grew them used to throw their old stock away after the plants had been two or three seasons in pots as large as they cared to give them. With the exception of such things as Azaleas and Camellias, the first hard-wooded plants on which I tried the effect of stimulants applied during the growing season were *Eriostemon luxifolius*, *E. neriifolius*, and *Boronia pinnata*, all old specimens that had been two or three years in pots as large as it was desirable to give them, and which had begun to make thin, puny growth, which showed that the roots had insufficient support. It was simply a question of putting them in the fire, or of trying to improve their condition by giving assistance to the soil. As soon as the growth began to move I gave them weak manure water made from horse droppings, with a dash of soot in it, and allowed to stand until it was quite clear; they were watered with this mixture once every ten days or a fortnight until

the last made young leaves had attained nearly their full size. At the end of the season all the three plants had made something like double the growth they had produced the year before, and bloomed well in the following spring. The next season the same course was followed with the plants named and a few others, and in addition a moderate dressing of Standen's manure was sprinkled on the surface of the soil two or three times during the spring and summer; by autumn when the growth was finished up, the *Boronia* had shoots from top to bottom 12 inches or 15 inches long, with flower-buds set at every joint. The growth made by the *Eriostemons* was equal to what it had ever been when the plants were in the full flush of youthful vigour. In the spring the sheet of flowers they and the *Boronia* bore was such as never had been obtained from young plants; and in this way they continued for seven or eight years in the same soil, when they began to get bare of foliage at the bottom and were destroyed. After this I gave the same treatment to most of the hard-wooded Cape and New Holland plants whilst in their younger stages as well as when they got old, in all cases regulating the strength and quantity of the stimulants given in accordance with the more or less free habit of growth natural to the kinds. A few things, amongst which may be named *Roella ciliata* and *Phenacoma prolifera*, did not appear to like anything in the way of stimulants. I tried most of the concentrated manures, but for hard-wooded plants generally, including Azaleas, I found nothing so effectual or so safe as Standen's manure. Later on the manure water used was urine from the cow-sheds largely diluted with water, being careful never to apply it until the urine was old enough, that is when it was from three weeks to a month old. Before this its use is dangerous; afterwards its effects are not approached by any of the many things I tried.

In private gardens, except to quick, vigorous-growing things, the use of manure water and concentrated manures, such as Standen's, nitrate of soda, sulphate of ammonia, and fish manure, is not so general as it might with advantage be. Probably there are no cultivators of pot plants who have so thoroughly mastered the use of concentrated manures as the market growers who supply Covent Garden with the marvellous examples of high cultivation, consisting of all the things they grow, from *Cyclamens* and *Pelargoniums* to *ventricosa* and *Cavendishi* Heaths. Through close and patient observation they know exactly the strength of the different manures they use that the different things they grow will bear. It is next to impossible to convey in writing the exact strength of the manure that any particular plant will bear, or the quantity of any concentrated manure that may be applied as a dressing. The only safe advice to give to those who have not experience in the matter is to be sure at the commencement to err on the right side in giving manure water to tender plants by using it weak enough, and to give little enough of any of the concentrated manures when sprinkled on the surface of the soil.

Psychotria cyanococca.—This stove plant is by no means remarkable for its blossoms, which are small and inconspicuous, but are succeeded by clusters of bright blue berries, which form just now a very attractive feature. As it fruits freely when struck from cuttings, small plants in 5-inch or 6-inch pots are very useful, as the berries supply a colour that is but little represented among stove plants, especially at this season. The leaves are about 4 inches or 5 inches long, light green in colour, and prettily crisped at the edges. It is a native of Nicaragua, and has been known in this country for

some time, but outside of botanic gardens it is seldom met with. This *Psychotria* is a plant of the easiest possible culture, for cuttings strike root readily, added to which it can be raised from seed. No particular soil or attention are needed, the principal thing being to give it a light position in the stove, in order to set the blooms and cause the berries to ripen.—H. P.

EXHIBITION SHOW PELARGONIUMS.

TIME was when judges at exhibitions, where show Pelargoniums formed a leading feature, in awarding prizes, required, above all things, form in the flowers allied to substance and smoothness of petal. It was for the attainment of these qualities that the late Mr. E. Foster and the late Mr. G. W. Hoyle worked assiduously during so many years, and produced so many fine varieties. But now that the bright, showy, and free-flowering decorative varieties have come to the fore, with, in many instances, fringed and serrated petals, they play an important part as exhibition plants, and produce

variety, that can be singled out for special excellence; it is of good habit and very free; and *Maid of Honour* (Foster), soft pink lower petals, dark maroon and orange upper petals and white throat, very fine and free.

It is a most embarrassing season for growers of Pelargoniums for exhibition. We get a sunny day or two, when the wind is soft and spring seems to have arrived; then follow dull cold days with icy winds. Whether to retard, or whether to push on, is a question very difficult to settle. So long as the temperature is equable, one knows what to do; but while such rapid changes occur, something like uncertainty of action must follow. R. D.

BEAUMONTIA GRANDIFLORA.

This plant, a truss of bloom of which is represented in the annexed woodcut, has hitherto been considered a very shy-flowering subject in this country. This is by no means the case with our plant at Panshanger, this being the

tained in all its freshness, whereas when out of doors it is often much injured by the cold winds. It forms a clump a good deal after the manner of some kinds of Iris, but the leaves are broader and more recurved. The flower-stems, which overtop the foliage, are terminated by broad, open panicles of blossoms. The individual blooms are star-like, about an inch in diameter, and pure white in colour, except the orange-tipped stamens, which stand out conspicuous against the purity of the rest of the flower. Like the old-fashioned *Agapanthus umbellatus*, this *Arthropodium* will flower in a far more satisfactory manner when undisturbed at the roots. In the shape of good-sized masses confined within pots a foot in diameter or thereabouts, a number of flower-spikes will be produced, and as the first blooms are now opening it will, under favourable conditions, remain in beauty a considerable time. Seeds are sometimes produced from which young plants can be raised, and, besides this, division of the roots is easily effected.—T.

Coronilla glauca.—Though a plant of very easy culture, this old-fashioned greenhouse shrub is now far from common, being probably in many cases driven from the field by the more robust *Cytisus racemosus*, which is grown in such numbers for Covent Garden Market. This *Coronilla* forms a handsome bush, equally effective and floriferous either in small pots or as large specimens. Besides the compact little heads of bright yellow flowers with which the plant is now thickly studded, the peculiar glaucous foliage renders it at all times very ornamental. This *Coronilla* may be classed among the more hardy greenhouse subjects, for even around London it will frequently survive several winters with the protection of a wall, and further south it is of course less liable to injury. At the same time, it is seen to the greatest advantage when treated as a greenhouse shrub, and under these conditions gives but little trouble, for insect pests seldom attack it, and, like many other greenhouse plants, it can be plunged outdoors during summer. Cuttings of the young shoots are by no means difficult to strike, and the plants are generally propagated in this way. Where it is necessary to limit the size of a specimen it may be cut back immediately after flowering.—T.

Rhododendron Dalhousiæ.—In the case of many of the beautiful Himalayan *Rhododendrons* it is necessary for them to attain a considerable size before they flower, so that a large structure is required to show them off to the greatest advantage; but, on the other hand, there are some that will bloom well when not more than a yard high, and to this class belongs *R. Dalhousiæ*. It is of rather a straggling habit of growth, and the roots are by no means vigorous, but these two features can readily be accounted for by the conditions under which the

plant grows naturally, for in a wild state it flourishes as an epiphyte, though in this country, with reasonable care and attention, it readily lends itself to pot culture. The flowers are borne in clusters, and individually the blooms are large and bell-shaped, and though varying a little in colour, they are, when first expanded, generally of a primrose tint, with perhaps a suspicion of green, but afterwards changing to white, or nearly so. Its free-flowering qualities have commended it to the hybridist, one of whose most successful productions has been *R. Countess of Haddington*, the result of a cross between this and the smaller-growing *R. ciliatum*. This hybrid is of free growth, retaining its foliage well and flowering profusely. The flowers are about intermediate between those of its parents, having the shape and almost the size of *R. Dalhousiæ*, with the pinkish tinge of *ciliatum*. Another hybrid is *R. Henryannum*, between *R. Dalhousiæ* and *formosum*. In growing the epiphytal species of *Rhododendrons* the conditions under which they are naturally found must be taken into consideration, and while the compost should consist principally

Beaumontia grandiflora. Engraved for THE GARDEN from plants sent by Lady Cowper. Flowers white (much reduced).

bold and striking masses of colour. When looking through the Pelargonium house at the Royal Nursery, Slough, recently, I found that nearly all the specimens being brought forward for exhibition are decorative varieties. They are *Decorator* (Hayes), crimson with maroon spots; very fine and highly effective. *Edward Perkins*, crimson-scarlet, with dark spots, an excellent variety and very striking. *Gold Mine* (Hayes), rich orange-carmine, very fine, and remarkably showy. *Kingston Beauty*, white with dark blotch, very pleasing. *Lady Isabel* (Hayes), lilac, with slight dark spots, a charming and exceedingly free variety that makes an excellent exhibition kind. *Madame Thibaut*, a pretty light semi-double variety with fringed petals. *Mons. Desmoulin*, deep rose with dark blotches, white throat, and petals with serrated edges. *Rosetta*, rosy purple with maroon spots, very free and effective; and *Triomphe de St. Mande*, deep crimson, a very good old variety.

Of what are known as the show varieties there are two very fine sorts; one is Foster's *Czar*, almost new, a singularly bright, high-coloured

fourth year of its flowering here, and each year surpassing the former in producing its grand masses of Lily-like flowers on the terminal points of the previous year's growth.

I find it a plant easy of cultivation, and although a native of India it does not require a great amount of fire-heat, but all the sun and light it is possible to give. Planted out in a soil composed of two parts fibry loam, one part peat, with a little silver sand, and treated similar to a well-grown Grape Vine, it will soon repay with a grand display of flower. Our plant is trained to wires 18 inches from the glass. After the flowering is over I prune it in rather close to produce young growth for next year's flowering. R. RUFFETT.

Panshanger, Herts.

Arthropodium cirrhatum.—This New Zealand Liliaceous plant is almost hardy in the southern part of England, but does best when treated as a greenhouse subject, for the ample foliage is then re-

pally of open fibrous peat and sand, ample drainage must be secured by means of broken crocks and a little charcoal mixed with the soil. As *R. Dahlbousie* is far from being a vigorous rooting kind, it is less fastidious in its requirements when grafted on a more robust species than when on its own roots.—H. P.

DOUBLE CINERARIAS.

"J. C. C." very properly called attention to the beauty and usefulness of these in a recent number. He explains the true secret of their freshness and beauty in a sentence thus—the plants in a cold frame shaded by a wall. A cool bottom and a shaded top are the chief conditions of success. But *Cinerarias*, double and single, are so extremely useful for house decoration, that almost as soon as they are in bloom they are set in the teeth of the sun and air in some window garden or greenhouse. From the moment they are thus placed they begin to deteriorate; the soft succulent leaves are drained of their proper juices or become a ready prey to thrips, fly, and other insect pests. These ungenial influences rapidly undermine the strength, mar the beauty, and end the life of the plants. In the case of single *Cinerarias* their fleeting character is of less moment. They fill a useful niche in decorative arrangements, ripen seeds, and disappear. As most of the finer strains reproduce themselves, or even improve if the seeds are skillfully selected, the old-fashioned methods of reproduction from suckers, root-division, or cuttings have almost disappeared. All this, however, must be reversed in the case of the finest double varieties. The more perfect the doubling, the less possibility of any seeds being saved from them. So-called double *Cineraria* seed is not infrequently more fruitful of very inferior single than of any double sorts worth growing. Either the seeds are very carelessly selected, or the tendency to revert to inferior single sorts is specially strong among double *Cinerarias*.

Either way, the only way to perpetuate double *Cinerarias* is through offsets, root-division, or cuttings, and to succeed in this with certainty a portion of each good strain or variety should be left in the cool pit or shady house until the propagation is completed. Collections of double *Cinerarias* have hitherto been rather unsuccessful on the whole. Some of the finer blooms have been associated with plants of rather weedy and lanky habit. Varieties also differ widely in stature and in character of growth, and, on the whole, the culture and general effect have seldom approximated to that commonly observed among single *Cinerarias*. Much of this inferiority has arisen from two causes, which, after all, both merge into one—a weak start with offsets or cuttings. Neither is the cause of the weakness far to seek.

Double *Cinerarias* are, on the whole, so novel and useful, from the staying properties and novel character of their blooms, that they have been placed in the most prominent positions. Not seldom has the writer seen them on dry shelves and in cutting draughts endeavouring to contract their evaporating surface to the narrowest limits by the violent flagging of their peculiarly vulnerable leaves. These processes daily repeated speedily weaken the entire plants, until root-stocks and offsets are either encumbered by disease or wholly destroyed. Not a few varieties are thus lost, and the stamina of the whole stock is seriously lowered through a weak start. The practical lesson is as obvious in theory as it has proved successful in practice—keep the plants set apart for reproduction up to their maximum health and vigour to the last.

To this end it may be needful to keep them out of the show and decorative races altogether. This will be all the easier accomplished if the flower-stems are removed from the plants reserved for stock so soon as they show. The effect of this will be to develop in abnormal numbers and to unusual strength offsets or suckers around the root-stock; thus by sacrificing a little bloom one season, we multiply many times the amount the next year, and ensure the permanence of any varieties worth growing, and may grow double *Cinerarias* with almost equal ease and success as single ones.

The two, however, are so different that the one should never be looked upon as a substitute or rival to the other, and in most gardens of any considerable extent there is ample room for both.

HORTUS.

Magnolia fuscata.—I notice in THE GARDEN of April 2 that Mr. Gumbleton takes "T. B." to task with respect to the above-named, and is responsible for the statement that it is "a low and slow growing bush not suitable for a wall." This cannot be accepted as an accurate description of the plant, for we have one here on the back wall of the Camellia house covering a space 10 feet by 15 feet, and it grows freely enough to cover a space three or four times this size. I find on measuring the shoots that the average annual growth is about 12 inches. Where anything showy is required, this *Magnolia*, with its small, insignificant-looking flowers, is naturally of little use, but there are many worse things for covering a bare wall, as the foliage is always bright and clean, and, so far as my experience goes, quite free from all insect pests. Perhaps the vigorous growth of *Magnolia fuscata* in our case may be partly owing to the heavy mulching of cow manure it receives when the Camellias are top-dressed. The scent of this *Magnolia* is very powerful; indeed, I think it one of the most strongly scented flowers in cultivation, the perfume from a single bloom being noticeable quite 20 yards from the house on a bright sunny day; I can detect very little scent during dull, heavy weather. The plant does not flower with us so well as it might under more favourable circumstances, its position on a back wall immediately behind some large Camellias preventing the thorough ripening of the wood.—E. BURRELL.

—In a recent number of THE GARDEN (April 2, page 304) Mr. W. E. Gumbleton gives some useful and correct information concerning the above seldom-seen plant. I should be obliged to him if he would supplement what is there stated by adding the most suitable temperature to grow it in. The only plant I ever had under my charge was grown in a stove temperature. It flowered annually and seldom made more than half an inch of wood a year, often less, and never failed to bloom, more or less freely, annually. The perfume when in an active volatile state is so potent and peculiar, as to be considered fulsome by the fastidious. More generally it is thought pleasant, and is one of the most unique odours among plants, its character being by no means exhausted by Mr. Gumbleton's vivid description.—D. T. F.

SHORT NOTES.—STOVE AND GREENHOUSE.

Gloxinias—These useful plants are now to be seen in great beauty in the gardens at Wykhiam Park, Buxbury. They are mostly grown in 9-inch pots, the plants being over 2 feet in diameter, and carrying from 80 to 120 finely developed flowers on each.—F. F.

Rhododendron Countess of Haddington.—A very fine specimen of this *Rhododendron* may now be seen in the gardens of Mr. E. H. Watts, Devonhurst, Chiswick. It is growing in a 16-inch pot, and is now carrying 150 trusses, each truss bearing on an average three of its beautiful white flowers.—W. T.

Aristolochia elegans.—I have several seedlings, and an uncertainty as to the soil required for their future treatment, and shall feel obliged if any of the readers of THE GARDEN will advise me in the matter.—F. LEACH.

—A coloured plate of this was given in THE GARDEN, June 19, 1886 (p. 570), and also a description of all the varieties at present known in gardens.—E. B.

Hovea Celsi.—I send you a photograph of *Hovea Celsi*, growing here. It is 10 feet high, and covered with its rich blue flowers.—J. THORPE, *Cuddington Hall, N. Crook.*

—A very pretty portrait of a most beautiful plant. We are sorry, however, that we are unable to engrave it, the flowers not being clear enough to do it justice.—E. B.

Bone-dust for plants.—Will some of your readers tell me to what uses among flowering plants bone-dust may be put, what plants it benefits or otherwise, and in what quantity it ought to be used? Would it not be beneficial for permanently planted subjects such as Narcissi, Lilacs, hardy herbaceous, and the like?—L.

Plumbago capensis alba.—I see this plant announced in a Continental catalogue, and would like to ask your numerous correspondents if any of them have flowered it, and if so, whether it is really white or only an unusually pale form of *P. capensis*. Should it be a pure white, this variety will be very valuable, but if only a washed-out tint it is useless.—H. P.

Salvia splendens alba.—Has any reader this variety, or is the reported white splendens a variety of *fruticosa* or some other species? I fancy there is also a white variety of patens. Information or cuttings of either would be much prized. By the way, is there any better mode of growing these winter-flowering *Salvias* than by planting them out in

the end of May a yard or so apart and potting them up early in October?—QUEEN ES.

CAMPANULAS IN POTS.

WHY these plants are not oftener seen in conservatories and greenhouses I fail to understand. We find them of very easy culture, very beautiful when either massed together or mixed among other plants, and fairly serviceable in a cut state. They are available, too, when there are not many *Azaleas*, *Dentzas*, *Cinerarias*, and other showy plants in bloom, and, on the whole, may be said to merit general cultivation and as much attention as any other class of plants that may be raised from seed. The earliest to flower are the *calycanthema* medium varieties, of which there are three distinct forms, viz., white, blue, and rose, the last being the newest, and the first the most valuable and serviceable. *Campanula pyramidalis* in two colours, white and blue, is quite distinct from the foregoing, being later, taller, and less branching, but more profuse flowering. Both well repay for good culture, and are within the reach of anyone possessing a greenhouse and a few frames.

We usually sow the seed early in April, but have been quite as successful in the case of *C. calycanthema*, with plants obtained by sowing early in May. The seed is rather small, but it rarely fails to germinate, a small packet giving enough plants to stock a neighbourhood. It should be sown on the surface of a previously moistened pan of fine sandy soil, and only a little sand distributed thinly over it. The pan of soil being already moist, no further watering or disturbing of the seed is necessary. Place the pans in gentle heat, or in a Cucumber or Melon frame, covering over with a square of glass and shading carefully. The pans being in a moist heat, and not exposed to sunshine or drying winds, little or no watering may be necessary till the seedlings appear, but they ought to be closely watched, as fine seeds are easily injured by drought. When necessary, water through a fine rose, or immerse the pans in tepid water. The glass must be removed from the pans soon after the seedlings appear, or otherwise the plants will damp off wholesale. When the seedlings are fit to handle they should be pricked off into pans or boxes of fine soil, and be kept rather close and shaded for a few days. They soon commence to grow strongly, and when large enough they should be planted out, as this will be found the best method of growing them to a useful size. They ought to be planted on a fairly rich, well worked border, and not less than 12 inches apart each way. During a very dry summer it is advisable to give them an occasional liberal soaking of water, but, as a rule, they require very little attention till the autumn.

Late in September as many of them as are needed should be lifted, no difficulty being often experienced in preserving a good ball of soil and roots, and potted into either 9-inch or 10-inch pots, according to the size of the plants. A good loamy soil suits them, this being firmly packed about the roots, and it is advisable to use clean, well-drained pots, especially if the plants have to be wintered in frames. We stand them at once on a bed of ashes in a cold frame, in which they remain through the winter, all the further protection needed being a liberal covering of either mats or straw litter whenever severe frosts are imminent. Last winter our plants suffered very much and lost nearly all their outside leaves. This did not injure them greatly, as they are now breaking into strong growth, and in the case of the *calycanthema* varieties, very branching flower-stems. Those who have plenty of room in various cool plant and fruit houses may with advantage winter their plants in some of these, and if well attended to and not smothered up by other plants, be rewarded with an earlier display of bloom. They, after active growth has recommenced, require abundance of water at the roots, as well as frequent supplies of weak liquid manure, and if in comparatively small pots and much root-bound, they may well be stood in pans of water, but this should not be resorted to as a rule. Our plants usually grow to such a size as to be too top-heavy for the pots, and are

literally one mass of flower from top to bottom. The white forms of both species are especially chaste and beautiful, the calycanthema varieties being most showy, owing to the calyx of the flowers being of the same colour as the flower proper. The latter ought to be grown by those who require abundance of white-flowered plants, either for grouping or cutting from at Whitsuntide. A few strong plants will afford armfuls of flowering branches, and these, if no heavier flowers are laid on them, will travel to a good distance fairly well. A well grown plant of *C. pyramidalis* ought to throw up a flower-stem at least 1 foot in height, and this will give hundreds of blooms, many of which may be cut with a fine stiff stem. The white variety is useful alike for vases, bouquets, or wreaths. After flowering all may safely be thrown away, seedlings being preferable to plants obtained from suckers. Quite small plants of *C. calycanthema* will flower, but late raised or weakly plants of *C. pyramidalis* will not do so, and must be kept another year; hence the necessity for making an early start and for growing the seedlings as rapidly as possible without actual stove treatment.

Both species are very effective border plants, and those not required for flowering in pots may be either flowered where grown or transplanted to positions where a display is needed. Frequently hundreds of seedlings will spring up in the autumn or early in the spring near where the old plants flowered and seeded, and these are excellent for preparing for pot culture. Some good cultivators raise their seedlings of *C. pyramidalis* in the autumn, keeping them in the seed-pans till the spring, and this is a good method of securing extra fine plants.

W. I.

AURICULAS.

SEVERAL inquiries were addressed to me at the recent Auricula show by persons interested in this flower as to where the new varieties that were so plentifully shown could be purchased. I could not reply to this question, as it may be years before a sufficient stock of some of them will admit of their being sent out. I could but assume that some, at least, of these inquirers were persons attracted by the unusual character and beauty of the flower, and were desirous of growing it. They thus stand in the relation of young beginners, and to such I would say make a commencement with some of the commoner sorts until you have ascertained whether or not you can grow them with success, and when you can, then add to your collection choicer and higher-priced varieties.

The choicer varieties of named show Auriculas appear to be scarce, for they are in constant demand. The propagation of any one of these is at best but a slow process, as they can be increased only by means of offsets, which are often produced very sparingly. The cheaper sorts are in less demand, and a collection sufficient for a novice to commence with can be got together at a comparatively small cost. Of green edges, there are Litton's Emperor, Smith's Lycurgus, Oliver's Lovely Ann, Headly's New Green, Ashton's Prince of Wales, and Traill's Rev. George Jeans. If he wishes to add something of a little higher class quality, Traill's Anna and Simonite's Talisman are good varieties. Such fine sorts as Traill's Prince of Greens, Leigh's Colonel Taylor, and Simonite's Rev. F. D. Horner still command high prices, and are likely to do so until some of the newer green-edged flowers find their way into the market.

In the grey-edged class some good flowers can be had at comparatively low prices, such as Headly's C. E. Brown, Walker's George Levick, Read's Dr. Horner, Chapman's Maria, Lightbody's Robert Traill, Campbell's Confidence, and Lightbody's Richard Headly. A few shillings more will secure Headly's George Lightbody, Kay's Alexander Meiklejohn, Lancashire's Lancashire Hero, and Simonite's Frank Simonite. The last four are the flowers of the flock, but those first-named are varieties that cannot fail to give satisfaction to anyone who grows them properly.

In the white-edged section there is ample need for some strong and decided white edges, as many

of them are weak in density of meal on the margin. A strong white edge is a lovely Auricula, and some very promising new additions to this section were recently shown at South Kensington, but it will be some time before any of them can be distributed. But such white edges as Heap's Smiling Beauty, Taylor's Glory, Hepworth's True Briton, Traill's Beauty, Lightbody's Sophia Dumaresque, and Read's Acme are by no means difficult to obtain. The newest in this section, viz., Douglas's Conservative and Mello's Reliance, are yet dear, but the former is becoming more plentiful and cheaper. Walker's John Simonite is a fine white edge, but, unfortunately, very scarce and dear.

Then of the self flowers, such good sorts as Spalding's Blackbird, Pohlmann's Ellen Lancaster, Campbell's Lord of Lorne, Turner's C. J. Perry, Campbell's Pizarro, and Kay's Topsy are all cheap and easily obtained. A little higher outlay will secure Simonite's Mrs. Douglas and Horner's Sapphire. It will thus be seen that a young beginner can soon secure a collection of Auriculas on which to try his hand and not spend a great deal of money in doing so.

And if he would add some alpine varieties also good exhibition flowers are now cheap, amongst them being Colonel Scott, Evening Star, George Lightbody, King of the Belgians, Mrs. Dodwell, Mrs. Ball, Mrs. Lumby, Napoleon the Third, Phoenix, Sailor Prince, Prima Donna, Tenniel, and Vesuvius, and a charming collection is thus provided. When once a commencement is made it is easy to add better flowers, as success follows efforts, and the ambition of the cultivator rises to higher levels.

R. D.

SEASONABLE WORK IN PLANT HOUSES.

CAMELLIAS.—Plants that flowered during February and March will now be in full growth; the conditions most favourable to its free development are an intermediate temperature, a moist atmosphere, and shade in bright weather. In dull springs like the present it is necessary to be more particular in shading plants that require this kind of protection than in bright seasons, inasmuch that when the young leaves have been made under an all but continuance of dull weather, they are proportionately less able to bear the sun's direct rays. Even when Camellias are grown under late Vines, in lean-to houses facing south it sometimes happens that the leaves get much disfigured by the sun before the foliage of the Vines is sufficiently advanced to give the requisite protection. Plants that flowered late and are pushing freely should be frequently examined to see that the soil in the pots is sufficiently moist, as, with daily syringing overhead the surface is frequently wet enough, whilst the ball lower down is so dry, that healthy growth is out of the question. When in this state, immersion of the ball for twenty-four hours in a tub of water is the best remedy. The worst instances of the roots of Camellias being dry below whilst the moist appearance of the surface is such as to give the impression that all is right may now and then be seen with large plants that have been a long time turned out in borders. When plants that are turned out in this manner begin to make short, unsatisfactory growth, no time should be lost in ascertaining the state of the border. Should it turn out to be dry, it takes an immense amount of water to moisten the soil. The best way to proceed is to make a shallow dam or dams round the border, filling up with water daily for a week or two. Plants that flowered through the end of last year will, if subjected to heat as soon as they had done blooming, now have their flower-buds in a prominent state, and will require a little consideration as to the time they are again wanted to bloom. Few things are more easily regulated as to the time of their flowering than Camellias, but it is only during the time that immediately follows the formation of the flower-buds that the period of their blooming can be accelerated in a satisfactory way by the use of heat; after the buds are formed they will keep on growing so long as the plants are kept in warmth; whereas, if they are turned out of doors, or kept cool by a free admission of air to the house in which they are located, and then are sub-

jected to heat in the autumn with a view to hastening their flowering, the chances are that many of the buds will fall off.

AZALEAS.—Any plants that have bloomed late should now be kept in a growing temperature. In the southern parts of England it is only in cold, sunless summers that fire-heat is required, as by giving only a limited amount of air, and this only in the middle of the day, sun-heat can be economised to do the work. Continue to treat in this way until after the buds are set and have attained some size. In the colder parts of the kingdom to grow Azaleas properly fire-heat is necessary, especially to plants that have flowered late in the spring, as without the aid of artificial warmth the solar heat is gone before the buds are sufficiently advanced to admit of the flowers attaining their full size, and to ensure the buds not going blind in winter. Stand the plants well up to the glass, keep the atmosphere moderately close and moist, with a thin shade when the sun is powerful. Stimulants, either in the form of manure water or some concentrated fertiliser, should be given to all plants that have fully occupied the soil with their roots; without this it is impossible to keep the growth up to the requisite strength.

NERINES.—A greenhouse from which these bulbs are absent in autumn is wanting in a section of the most telling plants that bloom at that time of the year. The little difficulty there is in growing them, and the comparatively little attention required to keep them in a thriving state, make it difficult to account for their not being more grown. Give enough water to keep the roots moving freely until the foliage has attained its full size and is fully matured. Syringe freely overhead two or three times a week, as unless the leaves are kept quite free from red spider the plants do not thrive so well. They cannot have too much light at all times, but especially from the time the leaves begin to move until they die off naturally.

HYDRANGEA.—This fine old plant is by far the most useful for conservatory decoration when grown annually from cuttings struck either in spring or in the autumn after the growth is matured. Plants propagated at the latter time usually give the largest heads of bloom, but spring is the most convenient season for many to strike them. Shoots that have sprung up from the collars of plants that have been forced will now be in condition for taking off; they are best put singly in small pots, as then no after disturbance of the roots occurs. When the cuttings are rooted and have got well established, it is advisable to put them at once into the pots in which they are to be grown and flowered; such as are from 5 inches to 7 inches in diameter are large enough. After this a cold frame with the pots plunged in ashes is as good a place as any for them until the roots have got well hold of the soil, when they may be fully exposed to the sun till it is necessary to house them in autumn. Any side growths that appear should be removed with a view to direct all the strength to the formation of a single shoot and head. The plant will bear much careless treatment, and still live and flower after a fashion, yet it is well worth the little extra attention requisite to secure the fine heads of bloom which it is capable of producing. If only for the length of time that the flowers will keep in presentable condition when stood in rooms and dark corners in conservatories where most other things could not exist, it is deserving of being well treated.

EPACRIS.—The later flowering portion of these plants should have their shoots cut back as they go out of bloom; after this if they can be located for a few weeks in a house or pit where the atmosphere is kept a little close by admitting no more air than necessary to prevent the temperature rising too high in sunny weather, it will help them to break more freely. Syringe overhead in the afternoons, but be careful that no more water is given than necessary to preserve a healthy condition of the roots, as these plants—always impatient of any excess of water—are still more so after their branches have been reduced. Epacris require

comparatively less pot room than the generality of hard-wooded plants, especially after they have attained something like specimen size; but in the case of young thriving stock it will not answer to restrict the root-space too much, or the growth will be weak and puny and will interfere with their flowering satisfactorily. Any that require additional room should have a shift as soon as they have made growth an inch long. After potting keep them closer and with less air for two or three weeks than at other times, likewise giving a thin shade when the sun is on the glass.

HEATHS.—Plants that were potted early in last month, and since have been kept drier than at other times, will now be in a condition to take water more freely, but it is necessary to see that they are not over-done in this matter, as if the new soil was to get too much saturated, the roots would not enter it, in which state they are all but certain to get into an unhealthy condition. An objection sometimes exists against the cultivation of these beautiful flowering plants, and arises through the erroneous impression that little use can be made of them for decoration when in bloom, through the notion that they do not like moving from the house or pit in which they are grown. Heath's do not well bear for any time a close, confined atmosphere, especially in positions either overhung or too much crowded by other plants, or when placed in a conservatory that is kept warmer than greenhouse plants require to be. In a house of this character where an ordinary temperature is maintained, and that admits a fair amount of light, Heaths may be kept during the three or four weeks they are in bloom without any danger of their suffering, particularly if a little forethought is exercised in selecting places for them where they will not be too far from the glass and where air is admitted. It is the indiscriminate thrusting of these and other light and air-loving plants into the positions in conservatories where they are supposed to be most effective, and where they are in a state of semi-darkness, or keeping them too long where some or other of the conditions essential to their well-being are absent, that is injurious. The sorts that flower in spring and summer especially can be made use of in the way under notice, as at these seasons the length of the days, coupled with the freer admission of air to the structure, is more in accordance with their wants than at other times of the year. What holds good regarding Heaths in this matter is equally applicable to hard-wooded plants in general which may be used for conservatory decoration without hesitation during the time they are in flower, provided the precautions indicated are followed and they are not kept too long in such quarters. It is scarcely necessary to say that if an *Aphelaxis*, a *Boronia*, or a *Hedera* were allowed to remain as long as their flowers were presentable in a house where the conditions to their future existence were wanting, much harm would be done, as their flowers, lasting, as they do, for months, would entail their being located in places where the growth that was in progress at the same time would be deprived of the light necessary to give the requisite solidity to the plants. T. B.

Education for gardeners.—I quite concur with the remarks of the editor in *THE GARDEN* (p. 374) when he says "a gardener should learn his own business well." "H. J. H." introduces rather too many subjects for the average gardener to master, and if "H. J. H." had a magazine introduced called "The Under Gardener," I very much question whether it would do much good, unless it contained a coloured plate and a column or two of "gardeners wanted." The majority of young gardeners care very little about reading; they are not picked from that class. I have found some young men study, but very few. Two who were under me, and who were of studious habits, are in first-class places to-day, and enjoy the confidence of their employers, but generally I find very few who care to read. I have sent *THE GARDEN* up to the young men's rooms every Saturday for the past eight years, and after a month's time I generally find it has never been cut. The coloured plate is looked at, and the remark passed as to whether it is a good one or

not, and then they look to see if anyone wants a gardener, and that is all they care about. I lent them the "English Flower Garden" to read, and after some time I asked how they liked it, and got for an answer, "It is of no use to a gardener; it is all about outdoor hardy stuff." Anything that will grow without a flower-pot, and without a shade to draw down every time the sun shines, is not worthy of their notice. My advice is to study geometry (a little), heating, geography, botany, and arithmetic. These are subjects which will not cost much to get a fair knowledge of. "H. J. H." says their means are too scanty to buy books; but books will never make a gardener, nor will a lifetime spent in the houses. The true gardener admires and loves the hardy plants as much as the most expensive *Cattleya*.—MILTONIA.

CHRYSANTHEMUMS.

E. MOLYNEUX.

THE plants now being grown for producing large blooms for exhibition or otherwise will vary in height from 1 foot to 2 feet 6 inches, according to the variety. If all has gone well with them since their propagation they should have one stem, and be furnished with healthy, stout green leaves, which should if possible be retained until the plants perfect their flowers. This can be done if all the necessary details of culture are attended to during their growth. If they are neglected and allowed to become dry at the roots, or mildew attack them, or if the plants are allowed to stand too thickly, the leaves cannot perform their natural functions, and are thereby weakened. Future success is largely influenced by an early disfigurement of the primary leaves of the plants. In many instances, such varieties as *Lady Selborne*, *Elaine*, *Baronne de Prailly*, *Triomphe de la Rue des Châlets*, for example, will now be making their first natural break into additional shoots beyond the number started with. This multiplication of branches is caused by the formation of a bloom bud in the point of the shoot. When this takes place growth is for a time at a standstill. After this bud is so formed new branches start from each joint below the bud; this is a critical period of growth puzzling to beginners in the culture of this flower. What to do with the new shoots is the puzzling question to many persons. Where the flowers are intended to be of the first order of merit, it is not wise to make provision for more than three on each plant, but where home use is the desideratum as many as six will suffice. The point, then, at this stage is to lay the foundation for future productions. As one bloom only of anything above average merit can be depended upon, it is therefore necessary to provide ourselves with as many branches as flowers are expected. In the case of the first number, the shoots to that extent should be retained at the time when the plant makes its first natural break, as pointed out previously. Select, then, the three uppermost branches, removing the flower bud and all other branches forming below the three left. In the case of the plants grown for home use only, the three upper branches should be retained in the same manner as in the former case, the additional number to be added at a later stage. Many growers pinch the point out of each plant at 6 inches or 8 inches high; the strongest shoots resulting from this topping are selected to the number of two, and by some three, but from experience I have found that plants which are allowed to break into growth naturally produce the best results. Plants that are grown for other purposes, such as bush, pompons, singles, and specimens, should have close attention as regards the pinching of the

branches at this period, as growth is now quickly made; neglect of this renders the plants taller than is wished for, and in such a manner they cannot be made to look so effective as where the necessary details are carried out at the proper time.

GARDEN FLORA.

PLATE 596.

PRIMULA STUARTI VAR. PURPUREA.*

THIS is Sir Joseph Hooker's name for the fine Primrose figured in the coloured illustration. The synonyms are *P. purpurea* (Royle), *P. macrophylla* (Don), and *P. Jaschiana* (Kerner). The following characters of the type and the variety are extracted from Sir J. Hooker's "Flora of British India," vol. iii., p. 490:—

P. Stuarti, mealy or not, quite glabrous, leaves 4 inches to 10 inches long, coriaceous, sub-erect, broadly or narrowly oblanceolate, or obovate spatulate, acute or obtuse, quite entire, crenulate or finely toothed, midrib very broad, petiole broadly membranous below, flowers loosely umbelled, bracts elongate, calyx torcite, lobes usually long, narrow, acute, rather obtuse; corolla yellow or purple, &c. Habitat throughout the Himalayan range at an altitude from 12,000 feet to 14,000 feet; also in Af. hanistan.

After long study I am unable to draw any specific characters between the many forms of purple and yellow (rarely white) Primulas included under the above character. If there are species among them they hybridise so as to defy recognition. Five varieties are described, each of which may have its small and great form with narrower or broader, entire and serrated, mealy and green leaves, many or few sessile or pedicelled flowers, more or less deeply cut calyx, mealy on the outer only or on both surfaces and a longer or shorter corolla tube with very variously formed lobes. *P. purpurea* generally resembles the type, except in colour, but sometimes has the flowers in two whorls.

The coloured illustration is a faithful copy of an oil-painting by Miss North, from a sketch taken by that lady of plants flowering in the garden at Edge Hall on September 15 of last year. It must be explained that by an optical delusion some of the right-hand flowers of the lower umbel appear to be united by branched pedicels. This, of course, is not really so, the pedicels being all one-flowered, and all uniting in the same point at the top of the scape, though it is difficult to trace them in the figure. The two plants were not growing together, but in different parts of a raised bed. The colour is the richest glossy purple. In some of the dried specimens in the Kew herbarium the individual flowers are much larger than those here shown. As regards cultivation, many of the Himalayan plants seem puzzled by the English climate. Some of the Primroses, as *P. denticulata* and *P. rosea*, are so hardy as to endure any rough treatment, even being cut to pieces through the crowns, and seem to thrive in spite of it. Others, like *P. sikkimensis* and *P. capitata*, are easy to rear to a first and second flowering, but not easily made true perennials. *P. Stuarti* is one of the less easy species to deal with in our climate. Seed of it is not sent in great abundance, and it does not ripen it freely in England. The seed, if fresh, generally comes up pretty well, but the growth is rather slow. Plants of it seldom flower here till they have passed through two winters. The root-stock is very liable to rot and destroy the plant in the second winter, and if they survive to flowering, this liability is much increased. *P. S.* var. *purpurea* is less easy to rear to flowering size than the type. The plants figured may be called lucky accidents of cultivation, for I cannot explain why these two flowered so well twice in the same year, and three or four dozen others which were treated exactly in the same way mostly died without flowering, either in my own garden or in those of my friends. The seed from which I raised

* Drawn by Miss North in the gardens of the Rev. C. W. Dod, Edge Hall, Malpas, Sept. 15, 1885, and printed by G. Severeigns.

them was sent from India in January, 1884, and raised without artificial heat under glass. When large enough they were pricked off into a box a foot deep, and were kept without shelter until winter, and placed under a light till the next spring. Then about May, half of them were planted in raised beds of equal parts of loam, peat, and broken stone; the rest were distributed; at the beginning of the winter of 1885 seven or eight survived, some being of large size. I covered most of these with handlights or inverted flower-pots, and by the middle of April the two plants here figured were in flower. One of the umbels was much larger than that shown, having more than fifty flowers. I could not, however, find any seed, though capsules were formed.

The same two plants flowered again, apparently from the same axis of growth, in September, and from this second flowering the sketch for the picture was taken. Several plants of the type *P. Stuarti*, from seed sown at the same time as *P. var. purpurea*, flowered last June. One of them after flowering produced fifteen new crowns; these I detached, and most of them flowered at the end of October. In other cases both the old plants and the young growths rotted away from no apparent cause, and with my present imperfect knowledge of its habits I must pronounce *P. Stuarti* one of the most capricious of hardy plants.

C. WOLLEY DOD.

FLOWER GARDEN.

PERMANENT FLOWER BEDS.

IN August of last year, a correspondent of THE GARDEN (page 195) asked if "some one would suggest any arrangement of plants suitable for permanent beds in a flower garden," in answer to which query I gave a short answer, intending when opportunity offered to go more fully into the matter, and as I have lately been engaged planting beds after that fashion, I make the effort to fulfil my intention whilst the matter is fresh in my memory. Up to a very recent period, consequent on the pre-eminence of summer bedding, by the term of "flower gardening," it was pretty generally understood to mean the bedding-out branch of it only; in fact, it was for a number of years so popular, that the younger generation of gardeners had come to regard bedding-out as the only proper style of flower gardening. However, we have advanced—are advancing—for now, instead of one prevailing phase of flower gardening, we are getting larger hearted, and are ready to find a place for flowers of every description. This is my case, but I would not have it understood that I thereby repudiate every description of summer bedding; as now circumstanced, I could not if I would, and would not if I could. I prefer reformation to annihilation, and the lines of reform I long since adopted were, as stated in a recent note, "the getting rid of as many tender plants and plants of transitory effectiveness as possible, and substituting hardy and long-lasting flowers and shrubs." The work of reform was at first difficult, because having, as I suppose everybody does, imbibed certain notions of what is proper, and the contrary, these what I may call fixed ideas took a lot of eradicating. I will give an instance, which is but an illustration of many similar ones. I have a particular liking for the white Japanese Anemone and for the yellow-flowered *Rudbeckia Newmani*, and had a strong wish to use both in association with summer bedding plants; but, strange as it may seem, I could not for years bring myself to see that they could with any degree of propriety be used with *Pelargoniums* and the like; and I doubt not but that there are many with similar ideas, and to such I would say, do not rely too implicitly on notions of propriety; anent this matter, as they will all vanish as soon as the experiment is made of planting herbaceous

perennials, shrubs, &c., in conjunction with ordinary bedding plants. But, notwithstanding that there is no incongruity in such mixtures, when permanent flower beds are in question, I would never think of using the ordinary run of summer bedding plants in such arrangements. The correspondent alluded to at the beginning of this note mentioned having *Rhododendrons* and *Azaleas* doing well, and by using the word "permanent," evidently wished for flowering plants as hardy as these, and probably intended any that might be named for intermixing with them. To this plan there is only the objection that both *Rhododendrons* and *Azaleas*—in good soil make such rapid growth, that unless they are distributed very sparsely indeed over the bed, they quickly overshadow and eventually smother slower-growing plants. Of course, this can be obviated by drafting the large plants every second or third year into the shrubbery, and using smaller plants from the nursery beds. More or less of this same sort of exchange will be necessary in respect of other plants, as they get too large or outgrow their position. This, though, is a very small matter, and not worth taking into account if contrasted with the labour necessary to obtain good floral effect for the summer season only. If these conditions (occasional change of plants) be recognised and acted on, there will be no difficulty in making an arrangement of plants, some or other of which would be in flower during ten out of the twelve months of the year. It is necessary to say that whatever number or variety of flowering plants may be used in such permanent flower beds, a small proportion of evergreen and ornamental deciduous plants ought also to be used, for the same reason as we use greenery in arrangements of cut flowers, and this will explain the presence of such plants in the list following. Supposing, then, that a number of large beds have to be planted on the lines indicated, *i.e.*, with a view of having flowers for the longest possible period, taking into account our uncertain climate, the following is the list of plants I would use, and which is entirely made from memory, so that probably some good kinds unknown to me are omitted. Of course, from such an extended list, smaller selections, according to size and number of beds to be filled, will require to be made. Evergreens, both for their flowers and foliage—*Rhododendrons*, *Kalmias*, *Andromedas*, and *Berberis Darwini*; deciduous-flowering shrubs—*Almonds*, *Azaleas*, wild *Cherries*, *Deutzias*, *Ribes*, and *Weigelas*; shrubs and small standard trees for foliage—*Acers* (*Maples*), particularly the finely cut and coloured foliaged varieties and the variegated kind, *Negundo variegata*, *Acacias*, *Liquidambar*, and *Sumachs*; small Evergreens for foliage only—*Aralia Sieboldii*, *Bambusa Metake*, variegated *Osmanthus*, *Vuccas*, and *Retinosporas*; dwarf evergreen flowering plants—*Heaths* (*Ericas*), *Irish Heaths* (*Menziesias*), *Helianthemums* (*Rock Roses*), and *Veronicas*; tall-flowering herbaceous perennials—*Helianthus* (*Sunflowers*), *Asters* (*Michaelmas Daisies*), *Tritoma Uvaria*, *Delphiniums*, *Solidagos*, *Galegas*, *Monardas*, and *Pyrethrum uliginosum*. The best herbaceous plants of medium height are *Aquilegias* (*Columbines*), *Spireas*, *Campanulas*, *Potentillas*, *Hemerocallis* (*Day Lilies*), *Phloxes*, *Oenotheras*, *Pyrethrums*, *Polemoniums*, *Staticeas*, *Japanese Anemones*, *Rudbeckias*, *Funkias*, *Iris*, *Lilies*, and *Paeonies* in great variety; the best dwarf-growing kinds are—*Anemone coronaria* (*Windflowers*), *Iberis* (*Candytufts*), *Primulas* (various, more especially the *cutusoides* section), *Hellebores* (*Christmas Roses*), *alpine Phloxes*, *Geums*, *dwarf Campanulas*, *Gentians*, *alpine Poppies*, *Silenes* (*Moss Campions*), *Trilliums*, and many others; the best of the more common dwarf flowers are—*Pansies*, *Violas*, *Pinks*, *Carnations*, and biennials in variety, such as *Wallflowers*, *Sweet Williams*, *Canterbury Bells*, *Snagdragons*, and *Pentstemons*. This is a list sufficiently comprehensive for the largest garden and largest beds or borders, without having recourse to undue repetition of kinds in any one arrangement, whilst for small gardens and beds from so long a list the grandest selection can be made.

ARRANGEMENT OF PLANTS.—In arranging the plants in the beds it is necessary to observe the fol-

lowing rules: First, to so disperse the various kinds of flowers over the entire bed, that at every season of the year there shall be an equality of flowers; secondly, that with the exception of plants that are used for their foliage only by way of enhancing the effect of the flowers, all others shall be grouped or planted in masses of from three to nine plants in each; and thirdly, that plants of the most varied characteristics, so long as they agree in height, shall be planted in juxtaposition, as, for instance, broad-leaved and robust-growing plants near those that have finely cut foliage and a more wiry growth. In arrangements composed solely of herbaceous plants the same rules should be adhered to, and in the more highly kept parts of the garden the bare soil beneath the plants and the outer margins of the beds will look all the better if clothed with the mossy-growing *Sedums*, such as *Glaucium* and *Lythium*. W. WILDSMITH.

THE NEW SNOWDROP.

(*GALANTHUS GLOBOSUS*.)

IN the last GARDEN I see a plant figured under this name, for which, I presume, Mr. Wilks is the sponsor. I shall be glad to know whether in his opinion and that of the editor of THE GARDEN, who I see still maintains a preference for English names, this name is to be accepted as a botanical name, in which case a more definite description should be given, and whether the provisional naming of plants which are of very doubtful specific rank is a practice likely to produce good results. *G. Elwesi*, like almost every other plant, is variable, but if Mr. Wilks will consult the figure and description of it in *Botanical Magazine*, t. 6166, he will see that there are characters of flower, leaf, and basal sheath by which it can be strictly defined, and which I have not known to fail either in imported plants or home-raised seedlings. His *globosus* seems to me but an inconstant two-flowered variety, and not a bit more globose than many plants of *G. Elwesi*. Had he not better cancel this name at once, and call it *Elwesi var. biflora hort.*, because in that case gardeners will know what is meant, and botanists will be saved the trouble of hunting up back numbers of THE GARDEN to refer to the description?—H. J. ELWES.

— Mr. Wilks writes as follows: "The name is by no means intended as an authoritative botanical name. I am not a botanist, only a humble gardener. I have examined thousands of *G. Elwesi*, and have a very large number growing in my own garden, and the flower in question is very distinctly and very greatly more globose than any single specimen of *Elwesi* which has ever come under my notice. No one need recognise the name *globosus*, as I have only given away one bulb of it to a great authority on Snowdrops, who considered the plant very distinct and concurred in the suitability of the name. Nothing would induce me personally to label such a lovely plant in my own garden as *Galanthus Mrs. Smith Jones*, or *G. Mary Anderson*, or any other English proper name—names whose significance will in a generation have quite passed away, while the plant will be fresh as ever. The editor of THE GARDEN is not in any way committed to my provisional name, nor to any of my opinions. The utility of such a paragraph as that in the last number was to elicit opinion and report a supposed novelty. Mr. Elwes, who has not seen it, considers it a variable form of *G. Elwesi*; I who have, do not."

** We do not clearly see why Mr. Elwes should raise this question about the new Snowdrop. The figure will remain, and we think, justify the name Mr. Wilks has given it, though it, like all other Snowdrops worth growing, must have an English name. Mr. Elwes can hardly suppose that people will go about mouthing dog Latin names for his Snowdrop or any other Snowdrop! Whether *globosus* is a variety of the one named after him or not we do not know; it is a point that can be tested. I believe the Snowdrop sent by Mr. Wilks to be a more beautiful one than *Elwesi*, and as a garden plant distinct. As a species also it seems to be as well marked as some of the other Snowdrops

supposed to be species. But what one botanist calls a species another does not, and from a garden point of view it does not matter one jot. Only a narrow pedant would contend that names in a foreign tongue are more necessary or reasonable than English ones. Whether plants differ as species or not matters little in the garden, as many of our best things are varieties—Gloire de Dijon Rose and the Weeping Beech, to wit. Ed.

Chionodoxa Lucilæ. The comparative merits of this plant and *Scilla sibirica* have been discussed from time to time, and while fully aware that the opinion of the majority is in favour of the newer introduction, under certain conditions I should give the preference to the *Scilla*. As bearing on the point I may mention that we grow them both here under exactly the same conditions in rather an exposed spot; and though the *Chionodoxa* flower just as freely as the other, they do not resist the strong cutting winds so successfully. This is owing to the weak flower-stalks of the *Chionodoxa*, which during windy weather sway about in such a manner that the flowers are often severely bruised, while the stout, sturdy habit of the *Scilla* enables it to bear these wintry blasts with impunity. Where as extensive a display as possible is needed for a small outlay, the cheapness of the *Scilla* compared with the other is also a consideration. The *Scilla*, too, can be forced into bloom by Christmas, but I have not yet succeeded in inducing the *Chionodoxa* to flower so early.—H. P.

Jeffersonia diphylla.—This plant, rarely seen in gardens now-a-days, although I believe obtainable at almost any nursery devoted to the cultivation of alpine plants, is for beauty both of flower and foliage unequalled by any other in character at the present time. The blooms are large, pure white, an inch or more in diameter, and have numerous conspicuous yellow stamens. The leaves are deep purple, as also are the stems, and the contrast between them and the flowers is most striking. It is found in North America in shady woods, and does well with us in a deep rich peat bed in a rather shady spot. Other plants nearly allied, which will grow well under the same treatment and have an equal claim on the cultivator, are *Podophyllum Emodi*, a Himalayan plant of rare merit, quite hardy in the open air, and accompanied after flowering by beautiful large orange-yellow or reddish fruits; *P. peltatum*, a very handsome large-foliaged plant; *Diphyllia cymosa*, &c., all of which may be grown successfully in a peat bed kept moderately damp.—K.

Anemone trifolia.—This species, which may be said to be nearly allied to our own native *A. nemorosa*, is in fine condition with us at the present time. Its mode of growth and general appearance, which are most marked when in flower, distinguish it readily when the two are placed side by side. *A. trifolia*, as its name denotes, has trifoliate, short, and very regularly toothed leaves, while those of our English plants are very irregular and resemble more nearly those of *A. ranunculoides*. The flowers are pure white, thrown well up above the foliage, but hardly so large as *A. nemorosa*. The latter, with its variety *Robinsoniana (azurea)*, are both seen far too rarely in gardens. When we see them in their wild habitats we think no amount of admiration sufficient to describe their beauty, though we hardly ever think of introducing them. Both are easily accommodated in ordinary soil, and well repay a little attention. K.

Double Polyanthes. It will be interesting to know how far the double *Polyanthus* Queen Victoria, crimson with gold lacing, differs from the old double Gold Bell of so many years' standing. Unfortunately, I missed seeing the double *Polyanthus* Queen Victoria. Gold Bell is said to be plentiful in the north of Ireland, a part of the United Kingdom that appears to suit it well. How seldom one sees the still older double dark *Polyanthus* or *flex* Theodore; it is said to have become very rare. I cannot grow it at Ealing, and I have made many attempts to do so; it is too hot and drying in summer. I have known semi-double forms come among the gold faced varieties, but

they are never worth saving, and I suppose we shall all be willing to admit that there is a great deal more beauty in a single *Polyanthus* of any kind than in a double one.—R. D.

NOTES ON HARDY PLANTS.

FRITILLARIES AND DAFFODILS. We have rarely seen two plants growing so well together as the common Daffodil and *Fritillaria Meleagris*. Intermixed in a rather damp situation in the Grass, the drooping chequered flowers of the *Fritillaria* contrast well with the yellow flowers of the *Narcissus*. It is only occasionally, however, that this will be seen, as the Daffodils are very late this season, and though now at their best, they have lost little of their colour as yet. *F. Meleagris* seems to be the only one that can be naturalised with any success. *F. imperialis* has been often tried, some few seasons with a little success, but mostly a complete failure; the majority seem to go blind from some cause which we fail to account for. The soil has been blamed, but it can hardly be this altogether, as they do very well in certain seasons. *F. pallidiflora* is a really good plant for borders, &c., and one of the best of them is *F. latifolia*, which is to all appearance a very large form of *F. Meleagris*. It seems to increase more rapidly than any of the others, and is much easier accommodated. *F. lusitanica*, *Moggridgei*, and others are worthy of attention.

AUBRIETIAS.—From the ordinary purplish flowers of the type to the new *A. Leichtlini*—exhibited from the Royal Gardens, Kew, at the Auricula show—a vast improvement has taken place, the course of which may be traced from the variety *Mooreana*, through *purpurea*, &c., to *Hendersoni*, *violacea*, and then to *A. Leichtlini*. The latter is certainly one of the finest acquisitions of late years to the hardy alpine garden, and, like the others, is quite hardy in the open air, and it will, no doubt, become a general favourite. A *violacea* is of a rich violet colour, but the new *A. Leichtlini*, raised by the gentleman whose name it bears, has rosy red in place of the violet, and when first open the colour is very striking indeed. In some cases, however, if too much exposed, the colour fades very quickly, leaving a washy pink, but this can be avoided by growing the plants in a sheltered spot on the rockery, or on overhanging ledges, &c., positions in which they will be very effective.

ADONIS VERNALIS.—This is really one of the most charming spring flowers we have seen this season. It is in full beauty at the present, sturdily holding its handsome large yellow flowers aloft in spite of the cold, ungenial weather we are now having. Its flowering at this time considerably enhances its beauty for the rock garden and flower border, and as it is easily accommodated in ordinary garden soil, we can strongly recommend it to lovers of alpine. Its near ally, *A. pyrenaica*, which flowers later, seems rather scarce; I believe from the fact of its being much more difficult to flower well. An importation from the Pyrenees last autumn seemed to be fine healthy plants when they arrived, but now, on examining them, I find many have succumbed to the damp, while those left are throwing up weakly leaves, and in all probability will not flower at all. The question of leaves seems to be the chief difference between the two species, *A. vernalis* having no root leaves, while *A. pyrenaica* has long, stalked leaves, those on the stem being sessile, or nearly so.

PRIMULA ROSEA. No *Primula*, in spite of the very numerous additions to our collections of late years, surpasses this beautiful species for open-air culture. It is undoubtedly one, if not the best, both for quantity and quality of flowers, and as it is so easily grown and can be raised so freely from seed, it should command a place in every garden where these plants are grown. On a north border, for want of a better situation, it does very well, as moisture seems to be the main essential to its welfare. A bog or marsh bed is its natural home, and here, if possible, with its roots in the water and the top fully exposed to the sun, it flowers with

remarkable freedom—sturdy, with the leaves reddish, and not pale green, as they are when grown under glass. The flowers grown in the open air are of a much deeper tint also than those we find under shelter, the stems shorter, and altogether in better character. The variety *grandiflora*, or *superba*, is of a much deeper tint, and if anything more robust. They both seed freely in the open air, and where patches have been grown we have picked up hundreds of self-sown seedlings.

PRIMROSES AT THE EXHIBITION.—Amongst the many beautiful *Primulas* shown lately at Kensington none attracted more attention than the new variety of *P. obtusifolia*, called *Gammieana*. It seems to nearly resemble a very deep-coloured, one-whorled state of *P. japonica*, and may after all be an outlying form of that species. The small *P. glabra* was also very interesting, too minute, however, to become of general interest to *Primula* growers; it seems to lie between *P. farinosa* and *denticulata*. The plants shown as *P. Kingi* and *P. reticulata* were nothing more nor less than *P. sikkimensis*, a species common enough to cultivation in our gardens now-a-days. *P. Kingi* more nearly resembles *P. Stuarti* than *P. sikkimensis*, and *P. reticulata*, though somewhat resembling *P. sikkimensis*, has much coarser, deeper, and sharper serrated leaves, the flower-stem as long again, less than half the number of flowers, and these being very small and of a poor colour. K.

Alpine Auriculas, shaded and unshaded.

—The remarks of "R." (p. 417) are called for at the present time. Nearly twenty years ago I urged the importance of raising alpine Auriculas, with the edge all of one shade of colour. I again took the matter up about ten years ago, one leading grower took the other side of the question, and stated that I advocated the introduction of alpine Auriculas with the leading quality left out. Since that time very few self-edged flowers have been introduced. All the varieties raised, either in the north or south, have been shaded. Quite a new type was introduced from France which was termed *laced*, a dubious name. Mr. Dean tried his hand at improving this strain and was very successful, but he seems to have dropped it. They were shaded-edged alpines, with the paler colour near the edge more clearly defined. It is supposed by the fanciers that the shaded edge gives a greater variety, and for pot culture I must confess that I like them, but to plant out in masses on the rock garden or in the flower borders the self-edged forms are most striking. I do not care anything for the double varieties either as pot plants or for the borders, with the exception of a semi-double golden yellow which has erect stems requiring no support.—J. DOUGLAS.

SHORT NOTES.—FLOWER.

Plants for rockery.—Would someone give a select list of plants for a rockery in full sun and partial shade? Also as to when such plants should be planted, and under what conditions?—L.

Golden-leafed Valerian.—The young foliage of this Valerian is very bright. Good sized clumps of it here are just now remarkably effective. It is only during the spring that this Valerian is of so conspicuous a hue, for as the season advances a great part of its beauty disappears.—H. P.

Arenaria balearica.—This is growing very freely in the rock garden, running over the faces of the stones and rocks; it is most persevering in its creeping habit, and we have some difficulty in preventing it from covering the gravel path in front of the rockery.—T. B. FIELD, *Stanley Hall Gardens, Bridgnorth.*

Hardiness of Passiflora cærulea Constance Elliott.—This supposed hardy Passion flower has been killed outright here this winter. It was planted out in a border, and trained up a wall that has a natural protection of shrubs all round, and it had a good mulching, but not otherwise protected. We are planting it again, and shall for safety give it the protection of a mat.—W. A. COOK, *Holme Wood, Peterborough.*

Double Primroses from seed.—Mr. B. Hooke, of the Towers, Hillingdon, has just sent me a truss of a double Primrose which he states came from some seeds of *Polyanthus* I sent him a few years ago. It somewhat resembles *platypetal a* and, like that variety, it throws *Primrose* flowers in single stalks and also trusses of bloom like a *Polyanthus*, but Mr. Hooke states that he has not this plant in his garden, and that what he sent to me was a *born tide* seedling.—R. D.

PASSIFLORA CERULEA CONSTANCE
ELLIOTT.

IN addition to the article which accompanied the beautiful plate of this in THE GARDEN of May 7, I should like to make a few remarks.

This plant was introduced to commerce by Messrs. Luceombe, Pince and Co. in May, 1885, and thousands of fine specimens at popular prices were then sent out from their famous and old-established nurseries at Exeter. On the 25th day of August, 1882, I found the original plant, which was at that time standing alone and apparently uncared for in the court at the rear of Mr. Fuller's house at Newton Abbott. It was not then in flower, but on the 13th day of the following month Messrs. Fuller and Son sent flowers of it, saying that they had raised it from the blue Passion-flower, and that it was the only one of the batch of seedlings. It was transferred to the Exeter Nursery, and a secure position against an outdoor wall was soon found for it, where it braved the inclement weather of that winter without protection. During the succeeding summer the plant became especially noteworthy on account of the extraordinary growth it made and the profusion of its delightfully fragrant white flowers. It was even at that time correctly predicted that the variety would prove an acquisition of the highest merit, and every means were immediately used to raise a large number of plants. It is easily propagated from cuttings. On the 27th of May, 1881, some flowers were, by desire, exhibited in London before the floral committee of the Royal Horticultural Society under the name of *Passiflora Constance Elliott*, when the much-coveted first-class certificate was at once awarded. This charming Passion-flower is now in constant request, the reason doubtless being that, in addition to its great beauty, it will flourish alike in the humble garden of the cottager as well as in the more elaborate gardens and conservatories of the wealthy. W. NAPPER, *Alphington Cross, Exeter*.

Your beautiful plate of this very useful climber in THE GARDEN, May 7, brings prominently into notice yet another hardy plant that will repay the shelter of a glass roof. Out of doors everyone is familiar with the long pendulous shoots of *Passiflora cerulea*, and have only to picture to themselves its white form to see the latest addition to this excellent class of plants, which, I may add, appear to thrive just as well in towns as in the country. It is late in summer before the young growths out of doors give a good supply of bloom; whereas by having a plant under glass one gets a supply of bloom very early in the season, as it is one of those plants that is almost a continuous bloomer. We have some plants now in full flower, the shoots as they grow forming bloom-buds in endless numbers. It is well adapted for wreaths, for although the stalks are not very long, the single blooms can be taken off and wired. It is of the easiest culture, and a plant not at all liable to insect pests. It is just the thing for lofty conservatories, where, after the main shoots get established, the growth of the current year can hang down in its own graceful fashion, and I am sure that anyone giving it a trial will not regret it. On the south coast, and especially in the Isle of Wight, wall climbers are more freely used than in any part of the kingdom I have ever visited, and it is surprising how beautiful even the most common-place-looking house is made by a covering of verdant foliage and beautiful flowers. Of course, many of the plants employed are not suited to northern gardens; but there is no lack of subjects hardy enough for any situation.—J. GROOM, *Cosport*.

Harrison's Musk for bedding. I am much surprised that your correspondent "J. C. C." in THE GARDEN (p. 370), is able to commend this plant as suitable for edgings to flower-beds. It is a pet plant of mine, and I have tried to grow it in every conceivable position, and complete failure has regularly occurred whenever that position has been an open one—that is, exposed to the full glare of the sun. In the far north and in rainy districts it would probably do well in such a position, but here it will not, no matter how unlimited the water

supply may be. The best, most pleasing, and effective use it can be put to in bedding arrangements is by way of undergrowth to tall-growing sub-tropical plants, no arrangement being more telling than with Gibson's Ricinus. The deep bronzy brown, both of stems and foliage, harmonises perfectly well with the light green foliage and yellow blossoms of the Musk, and the latter are larger, more profuse and continuous, by reason of the shade which the large leaves afford, as well as the shelter from heavy rains that in open beds batter down the flowers. W. WILDSMITH, *Heckfield*.

PRIMULA SIEBOLDI.

I NOTE the remarks by "A. D." on this *Primula* in THE GARDEN (p. 119), and give the reason why a larger number of plants of it was not exhibited. Up to the present season exhibitors were allowed to compete in the class for twelve species of *Primulas*, if they exhibited six distinct species; and as a result of this rule, as many as seven different varieties of *P. Sieboldi* have been shown in this class. For the present year an extension was made in the *Primula* classes. There was a class for twelve and one for six; in each class distinct species were required, and if more than one variety of *P. Sieboldi* had been exhibited in either class, the collection containing duplicates would have been disqualified. "A. D." is not very complimentary to my own collection of twelve distinct species which gained the first prize; all he has to say for it is that it contained "a huge *P. japonica*, with large leaves and a few poor flowers." *P. japonica* has large leaves, and the flowers of the white varieties are even smaller than the deep coloured varieties; but the plant was raised from seeds in our own garden in January of the previous year, and I am not sure that "A. D." could have done better in the time. We think it rather a remarkable plant, of course, as any one could see the spikes were not fully developed. I may say that unless a very large collection of species of *Primulas* are grown, it is very difficult to stage a dozen distinct species on a certain day in April.

Some growers were not able to exhibit even in the class for six. One would suppose that the rest of the collection contained "piny rock varieties, needing the aid of a microscope to discover their floral charms." In the first place, I do not know what a "rock variety" is. Does it mean the alpine and Himalayan species, the most piny of the *Primula* family, such as *P. Lurida*, grow in bogs? In the next place, I may say none of those were in my collection. All the plants exhibited by me were good specimens, with many trusses of bloom. I did exhibit one specimen of *P. Sieboldi* which was in an 8-inch pot, and had from twelve to fifteen trusses of bloom on it or more. The collection from Kew, so unceremoniously dismissed by "A. D.," contained the cream of one of the finest collections of *Primulas* in Great Britain, and added immensely to the interest of the show. There were classes of double and single *Primulas*, *Polyanthuses*, &c., for those who admire them, and I am sure no one would resent more than Mr. Llewellyn himself the remark that he alone brought plants, and other exhibitors pieces. In fact, my collection exhibited on the 26th contained larger plants, and occupied a larger space than any collection ever exhibited by Mr. Llewellyn. J. DOUGLAS.

White Daffodils and London clay. In THE GARDEN of April 30 (p. 388) Mr. Hartland observes that it is nonsense to talk of growing white Daffodils on the London clay. I most fully endorse that gentleman's words, and can only imagine that he has arrived at his conclusions after many and various attempts to cultivate these lovely flowers on the Irish clay. Whether in London or elsewhere, no one but a pure novice would ever make the attempt, for if we take the whole army of hardy bulbous plants many of them having vigorous constitutions—how many can be grown on clay, much less these choicer Daffodils. I know a provincial garden where even the Poet's Narciss will not do more than exist, the same garden growing herbaceous *Phloxes*, *Roses*, *Dodecatheon* *Jeffrey*,

anem, and many other things to perfection; the soil in this case is stiff, overlying blue lias clay. Surely Mr. Hartland does not wish to infer that white Daffodils cannot be grown near London at all? If so, then let your correspondent deepen his experience in this particular, and not thus dream of difficulties unknown, at least to the writer. Our soil is a beautiful light, fibrous loam, of which we have an average of nearly 2 feet deep, with a sub-soil of splendid gravel nearly 5 feet through. For upwards of fifty years this was one of many meadows belonging to a farm near by; hence we have an abundance of fine turf which is all turned in, and in this natural soil with a little cow manure added, clematis and its forms, albicans, tortuosus (syn. *Leda*), *moschatus*, *William Goldring*, and others revel; and, apart from our own stock of tortuosus, I had the pleasure a few days since of inspecting several thousands of its bulbs, which have stood for several years undisturbed, sufficient in itself to prove the fallacy of Mr. Hartland's remarks; these luxuriate in quite ordinary soil, and are about nine miles from Charing Cross.—E. JENKINS, *Hampton*.

MY AURICULA GARDEN.

THERE are some persons who appear to fancy that those who grow Auriculas under glass for exhibition purposes have no conception of growing them in the open ground. Really it is not so. There is scarcely one of us—perhaps not one of us—who does not grow Auriculas in the open border in addition to his choice collection in frames or in a house. Most of us are raisers of seedlings, and we raise some that, while not good enough to name, are yet too good to be thrown away, and the question arises, how best to utilise these. I do it in this way: I have a border some 12 feet by 6 feet facing the south, and raised some 8 inches above the path. It is edged with pieces of bricks, and over this kind of wall or fence falls a margin of *Amblycista violacea*, and so when heavy rains fall the soil is not washed down. Here, then, I plant out Auriculas, and they are just now in flower, and a very pretty sight they make; more than that, they give some useful seed. Then I have a mixed flower border, and alpine Auriculas make a very pretty and appropriate edging next the Box, and they are also used in many odd corners and places. When the Auriculas within doors are going out of bloom those outside take up the floral succession and carry it on some weeks later.

Now I plant out with some care, for I find this necessary. One has always by them some refuse Auricula soil, and this comes in very handy for the outdoor garden. I take out a good sized hole, and put some soil at the bottom; then the ball of roots is placed in it, and well lined with soil; some more is placed on the surface, and all is pressed down close together; finally, I give a surface dressing of Cocoa fibre. During the summer a top-dressing of soil is occasionally given. In this way I can maintain a very pretty outdoor Auricula garden, to my great delight.

I make this statement because it is thought that we Auricula growers are insensible to the beauty and usefulness of the Auricula in the open, and that we discourage attempts to grow it in this way. Why, the very reverse is the fact. The choicer plants are grown under glass, not because they are not hardy, but because they would flower in the most unsatisfactory manner in the open; and also because the rains, storms, and frosts of spring would rob them of their beauty. To me my Auriculas are a source of interest all the year round; and during the depth of winter, when they are at rest, they are yet able to attract the attention and regard of the enthusiastic cultivator. R. D.

Imported Hyacinth blooms. These appear to have been unusually abundant this year, as they may be found in every town and village in the kingdom. One may know them at a glance, for the sight of boxes full of flower-spikes packed like herrings without the slightest vestige of a leaf or green of any kind is anything but pleasant to the

eye. There is one side of the question that the Dutch growers appear to be overlooking, viz., if they swamp our markets with bloom the demand for bulbs must fall off, as an enormous quantity of bulbs are planted solely for supplying cut spikes, and at the prices these imported ones are retailed it is simply useless for home growers to try to compete. I am well aware that we have a goodly portion of the season still clear, but even if only a few weeks are taken off, the bulk of the trade in bulbs must be reduced.—J. G., *Hants.*

THE DAFFODIL COMMITTEE.

LIVING at a great distance from London, I find it now impossible to get Daffodil blooms to reach or be delivered by the postal authorities in time for the sittings on Tuesdays. I cannot post on Sundays, and even if I did they would not leave until Monday. It would be a great boon to parties thus situated if the hours for sitting were changed to 2 p.m. instead of 12 noon. In this way parcels will be surely in time from Monday's posting. There are a great many questions relative to wild plants to be settled—one in particular, the white Trumpet section. It is really puzzling this confusion relative to what is true *tortuosus* as distinguished from *Colleen Bawn* and *Leda*. The name *Colleen Bawn* first originated at one of the 1885 sittings with blooms sent from Ireland. From my point of view this plant has broad blue-green foliage, producing a snow-white flower rather late in the season and the outer perianth segments when you look at the flower fully having the twist of a ship's propeller, trumpet-shaped as a cylinder, and extended at the crown like the true form of *Haworth's bicolor*. Then, as regards the *tortuosus* of 1881 conference, this plant shows a facsimile bloom of *Colleen Bawn* in colour and foliage, and smaller, but the perianth segments are not so broad (snow-white in colour), yet lacking the propeller-like twist, and not so tall either as *Colleen Bawn*. Now, with regard to *Leda*, this plant has glaucous foliage, very tall, flowers when opening lemon-yellow, turning off to French white, not snow-white, as in *Colleen Bawn* and *tortuosus*, and many of the blooms having the appearance of a distinct flange at the crown, particularly when a little advanced in the season. The bulb of *Leda* is also quite distinct, being silver-skinned, like *pallidus precox*, and it blooms rather early. I have been doing my very best with large masses of the sections and noticing all their peculiarities, yet up to this have got very little assistance. I am half inclined to think they may be wild plants, but for their non-seeding properties, as wild plants seed so freely, while garden subjects are the reverse. Then, as a member of the Daffodil committee, I have been posting blooms to everyone who asks for them. I even went so far as to offer a five-guinea prize at South Kensington, to be competed for on the 12th of last month, for the best fifteen sorts of white Daffodils, three blooms of each, but failed to see a solitary entry, and for a bloom of the true *tortuosus*, as got from Tooting in 1881, I have searched two famous grounds near London, and could not see a sign of it, yet one firm offers it by the hundred.

Another set of Daffodils I want a word of controversy over; what is true *Haworth's bicolor* and *bicolor grandis*? Both are scarce plants and both have their substitutes; the true *bicolor* of *Haworth* is at Trinity College Gardens, Dublin, also at Temple Hill. I never saw it elsewhere, while the true *bicolor maximus*, or *grandis*, is at Temple Hill with its long, pale yellow crown and snow-white angular perianth segments so beautifully set and imbricated. It is from the back I know many flowers, particularly this one. Now the question for the Daffodil committee to settle is, what is the false Dutch *bicolor maximus* of commerce? Have we a place in *Haworth* for it? Exist it does, and existing there are two forms of *brevifolius*, and likewise a larger *tortuosus* of 1881 conference; I would like to call this the plant *Haworth* saw in photo., or used to dream of in stage-coach times; what joy he seems to have had at the rediscovery of ordinary *cernuus* in writing to the Rev. Canon Ellacombe, of Bitton Vicarage, in the year 1831. From my point of view

with this trial of white Daffodils, it matters but very little which of the lot we call *tortuosus*. Certainly the plant with the larger proportions, for the sake of fitting *Parkinson* and *Haworth*. If we grant this, the big one of all is at Temple Hill and snow white—evidently a wild plant, for it seeds freely, and up to this I have not sent it to South Kensington. The funny part about *Colleen Bawn* is this: at Manchester it is *tortuosus*, at Temple Hill it is *tortuosus latifolius*, while at South Kensington it has now been called true *Colleen Bawn*, and at Tooting I am told there is another *Dromo*.

Cork.

W. B. II.

PROPAGATING.

PANDANUS.—Seeds of many of the species are often obtained, and when such is the case all that is necessary is to sow them as soon as possible under the same conditions as Palm seeds. They should not be allowed to attain too large a size before potting them off, as the stout fleshy roots are very brittle and will bend with difficulty. Where seed is not obtainable, many of them (the dwarfier kinds especially) can be propagated by offsets; indeed, this is the method adopted for the increase of the variegated kinds. These offsets are generally thrown out just at the collar of the plant, and if it is potted deeper, so that the point of the junction of the offsets with the stem is completely covered, some of the shoots will form roots of their own, and can then be carefully detached from the parent plant and potted at once into small pots. Where the offsets are not already rooted, they should be detached with just a heel of the old wood, and potted into small pots in a very sandy compost. The pots should then be plunged in a bottom-heat of 80° to 85° in a close propagating case, when they will soon strike roots, and can then be shifted on into larger pots as required.

YUCCAS.—Generally speaking, the various kinds of *Yucca* are by no means difficult of increase, for most of them produce stout fleshy roots in the same way as the *Dracenas*. These roots, if cut off and placed under favourable conditions, soon form fibrous roots and push up a crown of leaves. From this circumstance it is often possible, should the specimen be in a pot, to turn it out, take off those stout creeping roots which in many cases will have made their way to the outside of the ball, and replace the plant in position without disturbing it further. Where the number is limited, a good way is to put each underground shoot in such a manner that its top, from whence the young leaves will be produced, is about an inch below the surface of the soil. The hardy kinds should, if possible, be sheltered by a frame till they commence to grow, and the greenhouse varieties push forth foliage all the quicker if given a little more heat than that in which they have been growing. The beautiful variegated forms can be increased in this way, and where there are any old, naked-stemmed plants of *Y. aloifolia variegata*, they can be cut down, and if the top is put in as a cutting it will soon root, and the stem can be divided into pieces about a foot long, which, if laid in *Coccoloba* refuse in a gentle heat, will push forth young plants from the dormant buds, and as the plants produced in this way form roots of their own, they can be potted off as soon as large enough. The old stems will often retain their vitality for a long time and produce several crops of young plants.

POINSETTIAS.—Where the old plants of *Poinsettias* have been kept rather dry after flowering, then shortened back, and placed in a moist growing atmosphere, they will be by this time studded with young shoots, which, when from 3 inches to 4 inches long, form the most suitable cuttings. They may be taken off at the point of union with the old wood, and inserted singly in small pots. The pots must be well drained, and the soil used of an open sandy nature, but sifted moderately fine. After insertion the pots may be plunged in a slight bottom heat, and kept fairly close and shaded till rooted. As the succulent shoots of the *Poinsettia* are liable to decay if kept too moist, care must be taken that

they are not over-watered, and at the same time, though in a close propagating case, a little air must be given in the morning to dry up any super-abundant moisture. As soon as rooted, they must be quickly inured to the air of the house, as a good deal of the success in their culture depends upon the encouragement of a short, sturdy habit of growth.

RHODODENDRONS.—The only class of *Rhododendrons* that have so far perfected their growth as to be suitable for cuttings are the hybrids of *Jasminiflorum*, *Javanicum*, and *Lobbi*. Where these have been kept during the winter in an intermediate temperature for the sake of their blossoms, many of the earlier shoots will be so far advanced as to have already lost their succulent character, and become slightly woody in texture. When this stage is reached they are then in the most suitable condition for cuttings, and in propagating these *Rhododendrons* it is necessary to catch the cuttings just at this particular stage, for if too young they are liable to shrivel up or decay, while if they are allowed to remain on the plant too long, the cuttings will often stand for months without rooting. From this circumstance a plant should not be allowed to perfect all its shoots before taking them off as cuttings, but rather the plants for propagating from must be looked over at this season about every fortnight in order to take off those shoots that have reached a condition suitable for cuttings. If not too long the cutting should be formed of the entire shoot taken off just at its base where two or three joints are crowded closely together. They should be taken off with a very sharp knife, and if a slice be cut from one side of the cutting for about an inch at its lowest part, a larger space for the production of roots is thus ensured. The soil for the cuttings should consist of very sandy peat and pounded charcoal or corks, the whole being sufficiently fine to pass through a sieve with a quarter of an inch mesh. A leaf or two being removed from the base of the shoot, it is ready for insertion, and as the leaves on the upper part tend to make it top-heavy, the cutting must be buried rather deeply in the soil. On this account a great many corks cannot be used for drainage, but if a good one is placed over the bottom the open nature of the soil will be sufficient; though except in the case of unusually large cuttings, a few more broken corks are beneficial. The soil must be pressed down firmly, and a little pure silver sand spread on the top. After a thorough watering the pots should be placed in a close propagating case, the best place for the purpose being that used for striking stove plants, as a little additional heat greatly accelerates the formation of roots. They will not be long in striking provided the cuttings are in a suitable condition. Grafting may also be employed for the increase of any variety, provided suitable stocks are at hand, but its principal use is for the propagation of those that do not root vigorously. The beautiful bright coloured *R. Duchess of Edinburgh* is one of these, and it will grow in a much more satisfactory manner when grafted than on its own roots. The older varieties, *Princess Royal* and *Princess Alexandra*, are generally used as stocks, the last from its vigorous habit being especially suited for the purpose. For grafting, the stock should be young and clean, while the scion may be slightly older than a shoot taken for a cutting. Side grafting is the method generally followed, and care must be taken that the two parts fit perfectly together. If this is done in a satisfactory manner, and tied securely in position, in about a month the union will be complete. After grafting the plants must be put in a close case and treated as cuttings till the two unite. As the confined atmosphere of the propagating case is very conducive to the increase of thrips, a sharp look out must be kept after them, as they soon disfigure the leaves if they are once allowed to effect a lodgment thereon. Besides these two modes of propagation this class of *Rhododendrons* can be increased by seeds; but, of course, they cannot be relied on to perpetuate any particular variety. As the varieties now in commerce represent the selected of several raisers, it is probable that out of a large quantity not one might be raised superior to, or even sufficiently

distinct from others in cultivation, yet the flowering of seedlings is especially interesting, and although they may not be quite up to the standard, are beautiful. If the earlier flowers were fertilised the seed-pods will be by now approaching maturity, and in that case they must be closely watched, as the pods will open and scatter their minute contents to the winds. Just as the seed-pod shows signs of cracking, it should be enveloped in muslin, or have a paper collar placed around it, to catch the seed. In sowing, well drained pots, or pans of sandy peat should be used, and being well watered the seeds may be sown thinly on the surface. From their minute character the seeds will not require any covering, except a pane of glass laid on the top, to be removed when the young plants make their appearance. When large enough they can be pricked off, and grown on as quickly as possible. It will be three years before they flower, and in some cases longer, but the result may possibly compensate for the length of time it is necessary to wait. T.

TREES AND SHRUBS.

W. GOLDRING.

THE SASSAFRAS.

(S. OFFICINALE.)

THERE is nothing particularly striking about the Sassafras as an ornamental tree, but it is of

is therefore effective when planted as a lawn tree, like one sees it at Syon, Kew, and several other places where old exotic trees abound. The illustration shows well the form of foliage as well as the flowers, which, by the way, are dioecious—that is, the flowers are male and female. The fruits are berries, not conspicuous, but somewhat like those of the Nettle tree or Hackberry (Celtis). The tree is only medium size. In its native habitat it grows, Gray says, from 15 feet to 50 feet high, and is common in rich woods, being especially abundant in North and South Carolina. In England it attains its fullest development, for some of the largest trees are quite 50 feet high. At one time it could be bought at nurseries, but since Loudon's time enthusiasm in planting ornamental trees has abated, and consequently it does not pay nurserymen to keep out-of-the-way trees in stock, so that when one asks for a really old and interesting tree, it is not to be got. There are, however, some slight indications that the demand for trees and shrubs out of the ordinary run is increasing.

Ribes aureum.—The flowering Currant (*R. sanguineum*) is everywhere met with, yet *R. aureum*, though equally beautiful, is to a great extent overlooked, being quite a rare plant compared with its

The Sassafras tree (*Sassafras officinale*). Branch, fruit, and flowers.

interest, inasmuch as it is one of the oldest foreign trees in English gardens. It was brought originally from North America as long ago as 1633, though it appears that it was introduced more on account of the medicinal properties it possesses than for ornament. It was known to the early gardeners, such as Gerard, who called it the Ague tree, its bark being employed as a remedy in several diseases, though its alleged extraordinary properties have since proved to be more apparent than real. As a cultivated tree it is not without merit, its leafage being handsome and of a peculiar soft yellowish green, that renders the tree distinct from most others. It

relative, though no reason exists why it should not be equally common, as both are plants of the easiest propagation and culture. The blooms of *R. aureum* are borne in great profusion, their colour being rich golden yellow, and besides this the bright, glossy, prettily lobed foliage renders it at all times an ornamental shrub. This glossy character of the leaves enables it to resist the smoke far better than *R. sanguineum*; indeed, I have seen it doing fairly well in towns where the latter could not exist. The genus *Ribes* is an extensive one, and though there are several kinds whose flowers are not particularly ornamental, on the other hand, many of them should find a place in any collection of flowering shrubs. The best would include, beside

R. aureum and *sanguineum*, the undermentioned varieties of the last: *atrorubens*, much deeper colour than the generally cultivated form; *albidum*, blush-white; *glutinolum*, lilac; *flore-pleno*, the flowers of which are double and later in expanding than the rest; besides *Gordonianum*, the colour of whose blooms suggests that it is a hybrid between the yellow and red-flowered kinds. In addition to these the Fuchsia-like *R. speciosum*, a strong-growing shrub with bright crimson coloured blossoms, is remarkably showy, the peculiarly spiny branches giving it a very uncommon appearance. Against a wall this kind will often flower quite early in the season, but does not bloom till May or June when planted in the open ground. It is seen at its best when in fairly good soil in not too hot and dry a situation. As a foliage plant, the golden-leaved form of the dwarf-growing *R. alpinum pumilum* is now very pretty, just as the clusters of young leaves are opening; indeed, during the first half of the summer it is seen at its best, as the foliage becomes much greener later on.—H. P.

TOP-DRESSING CONFERS.

FEW operations in tree culture are more efficacious than this. What a dusting of guano is in dripping weather to a green crop, that a dressing of fresh soil is to growing trees; it acts almost as suddenly, and its effects are far more durable. I believe, too, the action is compound; for the breaking of the turf over the roots of the trees seems to give nourishment to them, and it also cuts off such a greedy feeder as grass from the ground. And there is a stock of fresh food provided by the top-dressing, into which the roots rush up with a rapidity stimulated, one would think, by hunger. From whatever cause, this important fact is certain, that the roots almost follow the top-dressing, and the top mostly responds to them liberally the very first season; while the second gives even further proof of the effect of the dressing.

I was convinced of the great utility of the system by accident. Having occasion to level the surface of a pinetum, the peculiar position of many of the trees compelled me to level up, not down. The consequence was an accumulation of soil in some quarters from 6 inches to 30 inches deep. This latter I was somewhat afraid of. Roots buried so deeply might refuse to feed on the new or, indeed, on any material. These fears, however, proved entirely groundless. The deeper the dressing, the better the trees grew; not, however, that I would recommend any such depth; from 6 inches to 1 foot is sufficient at any one time. But, nevertheless, such was the fact. Ever since then I have been a convert to top-dressing Confers. To keep them growing at maximum speed, dress every third year; or if express growth is desired, and the trees are on the turf, dress every year.

Thousands of trees in isolated positions on the turf are simply starving into Moss-covered dwarfs. The original larder below is emptied of good things, and the Grass above is robbing the roots. Hence the weakness, leanness, and stuntedness of the trees. If a top-dressing of rich soil be given, the roots as well as the top and side branches will be much benefited. Remove the turf, cutting it thin to avoid the surface roots. Apply the dressing, and relay the turf directly. Where there is no turf, the operation is still more simple. F.

Andromeda japonica.—Apart from its beautiful blossoms, this evergreen shrub when in a young state has very handsome foliage, especially at the present time. Some specimens here, which have been rather sheltered and are consequently in a more advanced state than those fully exposed, are thickly studded with young shoots from 2 inches to 4 inches in length, the foliage on which is of a bright bronzy crimson colour, which at a little distance causes the bush to appear densely covered with bright coloured blossoms. This is by no means the only member of the Ericaceæ whose young growing shoots form such a prominent feature, some of the Himalayan species of *Rhodo-*

dendrons being a case in point, as in them not only are the young leaves brightly coloured, but the bracts that encircle the leaf-buds are equally effective. T.

Magnolia conspicua.—When paying a visit to the gardens of Digswell House, Herts, the residence of Mr. Brown, on April 21, a fine tree, about 20 feet in height, of the above was in full flower and presented a grand appearance, being literally covered with its pure white Tulip-like blossoms. After the severe winter we have just passed through it struck me as being more hardy than is generally supposed. No deciduous tree that I am acquainted with could be more beautiful at this season of the year. It requires to be planted in a sunny sheltered position, and the flowers are also very valuable when cut, as they last a long time.—EDWIN BECKETT.

Exochorda grandiflora.—In no collection of flowering shrubs should the Pearl Bush, as this is called, be omitted, for the beauty of its blossoms is further enhanced by the fact that they are among the first of our hardy shrubs to make their appearance. A suitable setting for the beautiful white blossoms is furnished by the delicate green of the unfolding leaves. In the open the flowers of this bush are sometimes injured by late spring frosts, but though to a great extent protected when treated as a wall plant, the light and graceful character of the entire specimen is lost. The fact of its being by no means common can be accounted for from the difficulty attending its propagation, as cuttings very rarely strike root, and layers are a long time before they can be removed. T.

KITCHEN GARDEN.

W. WILDSMITH.

TRIFLES AS APPLIED TO KITCHEN GARDENING.

I BELIEVE that attention to so called trifles in kitchen gardening is essential to success, and no season of the year could be selected better suited to illustrate and enforce this doctrine than the present. In days gone by there may have been gardens with men sufficient to keep all in good order without having recourse to the scheming and forethought that in these high-pressure, short-handed times is necessary to keep up a full supply of vegetables and the garden generally in neat condition. I know of no garden that can boast of such circumstances now; hence the necessity of forethought and of forecasting our work that no time may be wasted or crops suffer from timely lack of attention. This bright, the first real spring, morning (May 7) is welcomed, but the welcome is not unmingled with sadness in prospect of the difficulty of coping with the work that will quickly follow consequent on the change in the weather; but the practice of attention to trifles will greatly help us, and we shall commence with surface hoeing to kill weeds in some instances before they are visible, for my faith in this practice is so strong that during the summer-time it is no unusual occurrence for all hands to be told off on a hot sunny day and keep on till every bit of ground that it is possible to hoe has been gone over. Thinning out of seedlings is another of the trifles that we never postpone except when the ground is so dry that the work cannot be done easily without injury to the plants that are left; then, perforce, we must postpone till rain falls. The importance of an early attention to this matter of thinning is apparent from the fact that the work can be done much more rapidly than when the roots have got entangled together. Several kinds are now ready to thin out, such as Lettuce, Parsnips, and Turnips. Another important trifle is never to allow an exhausted crop to remain on the ground a day after that state has been reached, for even

if the ground be not wanted, unnecessary impoverishment of the soil is going on, not to mention untidiness where neatness might reign at the price of simply clearing the refuse to the rubbish heap. Our ground is, I was going to say, always newly cropped before the old one has been cleared off, and such is virtually the case, as succeeding crops are decided on long before the old crops are off, so that gardens of restricted size have their merits, contributing as they do to the exercise of one's mental faculties, and therefore to a higher state of cultivation. Over-production, too large a supply of vegetables, occasionally does happen from the vigilance thus exercised, but that, I contend, is a good fault, and all the writing to the contrary will never deter me from striving to get as much off the ground as possible. Other small matters that, so far as our kitchen garden work is concerned, are now needing attention are, indeed, but trifles; yet if neglected say for a week or ten days, the consequences will be increased work, some amount of injury or check, and, not least, a personal uncomfortable state of mind. There is the planting out of Tomatoes that have got pot-bound whilst waiting for fine weather that the work might be safely done; Peas to stake; drills in which we planted Cauliflowers to fill in now that rain has fallen—a procedure that serves as a mulching and prevents the necessity of watering, and also of earthing up; early-sown Broccoli plants and Savoys to thin out before they get damaged by overcrowding, to plant some of the last-named on the ridge of Celery trenches whilst the ground is moist; Strawberry plots to weed and re-mulch with long stable litter, that it may get washed by rain before the blossoms open; Potato haulm, protection from frost, is as yet a daily anxiety and labour to keep covered up. To conclude, it is largely the pleasure derivable from seeing all crops flourishing that enables us to pay such close attention to details of cultivation.

Beek's Dwarf Green Gem Bean is not nearly so much grown as its merits deserve, as it is one of the most prolific and useful of the whole of the Broad Bean tribe. The space required for a row is very small, and the Beans are of the size that rank them as first-class vegetables. It is by no means a new thing, but somehow it has never become generally known or grown. I find it answers better for successional sowings than the larger kinds, and a few rows may be grown on borders or positions where the tall kinds could not be utilised. When cooked it retains its beautiful dark green colour, which is such an attractive feature in good vegetables.—J. G. H.

Vegetable prospects.—In THE GARDEN of April 30 (p. 391), "Hortus," in an article on this subject, states that it will be long past midsummer before he can cut spring Cabbages. I should after that time most unhesitatingly put them down as summer Cabbages. If such be the case, better not grow spring Cabbages at all when we have a Cabbage that can be grown to perfection in about four months and under. I have grown Sutton's Little Gem to maturity in that time. The Cabbage that has stood the past winter here with impunity is Ellan's Early, of which I have already cut nice little hearts. I have another plot of the same Cabbage with several others, all of which have bolted, thus showing the great necessity of making two sowings to stand the winter. I have been cutting Broccoli for some time. The sorts that stood best are Carter's Late White, which stood well, I having only lost 5 per cent.; of Veitch's Model I lost 10 per cent.; Knight's Protecting I have lost 25 per cent., and some others swept clean off. Chou de Burghley and all the Savoys were killed outright. The Broccoles have stood well, as also have all the Kales. We have had a continuous supply of Brussels Sprouts since last September, and Cauliflowers and Asparagus are now making rapid strides, so that we shall soon again

hear less murmuring about the past winter. Peas with me have come up rather badly (maincrop varieties). Early Peas sown in February are looking well, and with fine weather will soon be in flower. Lettuces have stood very well. I grow a selection of the old Brown Cos. Fruit trees look remarkably well in this district.—W. A. COOK, *Holme Wood, Peterborough.*

HOME-GROWN I. MARKET VEGETABLES.

A CORRESPONDENT, who some years ago soliloquised over that early importation of Pines from St. Michaels, was, no doubt, quite correct, and within his right in stating that the culture of English Pines was doomed; but when he took this fact as his text for asserting that British gardening generally is going to the dogs, it might have been as well had he kept the matter to himself or made a note in his diary for the benefit of the coming New Zealander. That gardening, like all other matters mundane from the time Eve picked the first Apple down to the advent of Gilbert's Jubilee Chou de Burghley, has undergone many changes, no one for a moment will deny; but few, I think, will agree with "W." in his assertion that the thousands and tens of thousands of well-to-do owners of gardens in this country will turn these pleasure-giving spots into hen-yards because vegetables of a certain quality can be bought at a cheaper rate than they can grow them.

Assuming that every well-to-do owner were living within reach of a good market, a very small percentage might risk the destruction of their digestive organs through patronising those narts, and very wisely they would act by making homeopathic dishes suffice. But, apart from the immense pleasure which they derive from their gardens, the majority who have been in the habit of eating fresh, sweet, succulent vegetables would insist upon having their home-grown Potatoes, Cauliflowers, and Peas, and the men who could not supply them from frames or warm wall borders, which I maintain are better than hedge or tree shelter, would soon have to make room for others capable of arranging their crops to meet without waste the requirements of the household. Possibly some of these might cost five, or it may be fifty, per cent. more than they could be bought for, but from this source they must come or be dispensed with, and surely "W." will not insult his brethren of the blue by asserting that a fresh sweet Savoy from the home garden is not better than one that has travelled by rail or road to the nearest market, and after sundry pitchings and handling requires cooking with an extra grain or two of soda. Good gardeners do not grow Broccoli by the thousand or Cabbages by the acre unless they are wanted; neither do they go into the culture of Peas that are not worth the sticks, otherwise how does it happen that they carry off all the leading prizes at the shows and gain for themselves the well-merited character of first-class cultivators?

Stripped of its verbiage, "W.'s" last lamentation amounts to this, "Can Mr. Coleman tell us what becomes of the thousands of Broccoli and acres of Cabbages," &c.? Willing as I am to answer all reasonable inquiries and queries, never having grown or encouraged the growth of a plethora of common vegetables, I do not feel bound to answer that question. If I could show that they might be disposed of at a fair profit, I might live to see my statue erected in Mud-Salad Market, as every trade grower would contribute a trifle towards its cost. This honour, however, I do not covet, and as "W." is inspired, I will leave him to solve it in his own way. Meantime, the owners of gardens, according to his own showing, having become so thoroughly commercial, if not parsimonious, perhaps he will explain how, only last week, they flocked to Downside, Leatherhead, by trainloads, where, for duplicate Orchids, they paid sums varying from ten to three hundred and ten guineas. Whilst shrewd gentlemen, who know what they are about and how the pulse of the nation beats, can afford to pay three big figures for a small plant that might be packed in a hat-box, "W." may safely take fresh heart, for, bad as the times are, men much younger than either of us will live to see their grandchildren digging

home-grown Potatoes from frames and cutting delicious Cauliflowers from cap-glasses.

WILLIAM COLEMAN.

A SUCCESSION OF CELERY.

GOOD Celery is always a valuable vegetable, as it commands a high price in the market, is much appreciated in the kitchen, and it can be sent to the table cooked or uncooked. Stewed Celery is a most delicious vegetable, and although professional cooks use it largely in this way, I do not think small families fully understand its value in this form, or a succession of Celery would be a leading desire with all cultivators. In fact, in places where the value of Celery is thoroughly known it can never be ready too soon or preserved too late, and by giving attention to successional culture it may be had in good condition from July until May. Those who plant one good batch of Celery and think they have done their utmost with it are mistaken. It ought to be grown in three distinct lots—one for use from the end of July to November, another from November to March, and a third from March until May. One plan is to sow seed for the first lot, take the foremost of the plants in hand as soon as they can be handled and allow the others to remain crowded in the seed quarters for some weeks, and then transplant more of them to form a second batch of plants. But this system is never satisfactory, as although the first lot of plants may do well, the second batch is sure to show the effects of crowding and retention in the seed-pots or boxes by seeding prematurely. The earliest crop should be sown in February and planted out about the beginning of May, but the later crops are sown too soon as a rule, and more dwarf and better plants would be produced if sowing was deferred. All Celery will gain maturity in four months after sowing, especially in the summer season of the year, and instead of sowing November Celery in April, as is often done, the end of May or any time in June is soon enough to sow it. April-sown plants, which are not required until November, will be ready for use in September, and after gaining maturity they will have to remain on at a standstill until the winter, and this is not in favour of their keeping well, but if they do not gain their full size until November they enter on the winter in prime condition, and there is no difficulty in keeping them in first-rate condition. A great deal of Celery becomes soft and spongy during the winter. Many cannot account for this, but I think too early sowing and having the plants ready before their time is the main cause of it, and an easy remedy is in the hands of everybody. Spring Celery, too, is often ready for use in the autumn or early winter, and it is much against it that it should be kept dormant for some months before it is used, but if sown in July and grown so as to have plants about half or three parts their full size by November, it will grow on slowly during the winter and turn out first rate in the spring. It is now too late to give any hints as to the sowing of the first crop, as, like scores of plants we possess at present, they should be ready for planting at once. They should be put in double rows in trenches 8 inches or 10 inches deep and 18 inches wide. Give them abundance of manure, as there is no danger of their being forced on too fast; transplant with good balls of soil attached to the roots; tread the soil very firmly round them immediately after planting; place a little short manure between the plants as a mulching, and water copiously in dry weather. In this way a fine crop will quickly be produced. Now comes the second crop. After the month of May it is not necessary to sow Celery seed in heat; it may be sown in a cold frame, under a handlight, or in the open air, and the July sowing should always be made in the latter position. The seed should be sown very thinly, and only covered over to a depth of a quarter of an inch in rather rich soil. As many frames are now being emptied of bedding plants, if one light can be given up to the Celery seed, it may be sown thinly, and the plants allowed to remain until planted out in the trenches, but they must never be allowed to become crowded, and if there is any indication of this, draw the large ones up, and plant them about 3 inches apart elsewhere.

They will succeed if treated like Cauliflowers while young on any warm border, and those hardy-reared plants very often prove the most compact and robust throughout their growth, as plants reared in heat are always apt to receive a check unless they are well and carefully hardened off before planting out. Celery being planted now may follow Broccoli or any crop that has served its purpose, and the later crops can follow Potatoes, Peas, and such like. A rather light soil, free from grubs, is by far the most suitable for Celery. I have recommended a good deal of manure to be used with the earliest Celery, but the second crop should not have so much, and the third still less, as manure forces it into very luxuriant growth, and although this is very desirable where quick returns are the aim, compact and substantial growth is the hardiest and best for standing the winter, and when that proves severe or the district is a cold one, those points are more valuable than luxuriant growth. CAMBRIAN.

The hardiest vegetables.—I thank "W. L." (p. 390) for the generous manner he criticises my writings, and also for the good word he gives your readers on the Jubilee Green. But at the finish "W. L." says Chou de Burghley is not so hardy as I would have you believe. I send you two plants which have with some thousand others stood the winter in an exposed place; you will see what they are like. If Chou de Burghley is not hardy, I then confess I really do not know what is. R. GILBERT.

* * * The plants sent did not appear to be the least injured. Ed.

Market Cabbages. At a time when even with the exceeding dearth of white Broccoli seen everywhere in home market gardens, such good greens as Purple Sprouting Broccoli are selling at from 6d. to 9d. per bushel, it is evident that material which has to be a year on the ground, dating from the time of seed sowing, can hardly be profitable, let the crop be ever so good. But whilst there is an abundance of Sprouting Broccoli and heads of white Broccoli from warmer climes, good hearted Cabbages are scarce, and when good obtain fair prices. Of course, the chief difficulty to surmount, even with such hardy things as Cabbages, is the bringing them safe through the winter unharmed, and only the hardiest kinds will so stand. But there is something to learn in respect to time of planting out, for if the plants become too large they suffer from frost and snow terribly, whilst if too small it is then difficult to market them in the spring in time for another crop to follow; and that is important, because a late-gathered spring crop means the loss of the season for the year. Large heading kinds do admirably where sheep can follow and clear off the refuse, but for a profitable market the best are those of moderate size turning in very early and planted up thickly, so that no ground is wasted. It is hard to name kinds that may be found specially suited for this sort of work, because all may not be precisely hardy on diverse soils; but there are plenty of such, as any market grower can soon ascertain from his seedsman. In ordinary seasons the first week in August is a very good time for sowing seed, and the third week in September for planting out, following upon Potatoes, the soil being light and deeply worked. Such a crop should have headed in by the middle of May. A. D.

SHORT NOTES.—KITCHEN.

Chou de Burghley.—Having now grown this vegetable four years, I am able to endorse all that Mr. Gilbert has said in its favour. I certainly find it one of the most useful vegetables I grow, and should not like to be without it. By sowing twice, first about the middle of March and again the second week in May, we are able to cut Chou de Burghley from the beginning of October till the end of March. I find it very hardy, more so than any Cabbage I know.—R. G. G.

Seedling Cucumbers.—I send you a Cucumber, the result of a cross between Tender and True and Improved Telegraph, the last named being the seed parent. Will you kindly give me your opinion of it? I have been cutting for the past three weeks fruits from 1½ inches to 23 inches long. —STEPHEN CLARKE.

* * * The Cucumber sent was a very fine sample, but no improvement on existing varieties.—Ed.

The best position for Lettuces.—Lettuces vary very much in quantity and quality according to the position in

which they are grown. No one need ever expect to get good Lettuces from poor soil, and they absolutely refuse to become of any merit where the earth is very shallow. I have tried them in all positions, and for several years past we have invariably secured the best of our Lettuces from the ridges between the Celery trenches. It is astonishing how large, crisp, and fine they grow in this position, and were I asked to grow the finest Lettuces I could possibly produce, I would never wish to grow them in any other position than on a Celery ridge.—J. MEN.

KITCHEN GARDEN NOTES.

PLANTING AND THINNING. At last we have been favoured with sunshine and showers, the perfection of weather in which to plant out Cabbages and Cauliflowers, and thin out Turnips, Spinach, and autumn-sown Onions. This is the last planting of Cabbage we shall make till the autumn, but another small planting of Cauliflower Dwarf Erfurt (spring sown) will be made, and after that two or three plantings of Autumn Giant Cauliflower, the best of kinds for late summer and autumn supplies. The plants have just been pricked out on a warm border, and will be ready for the first planting out in about a month. Turnips Early Milan and Early Munich have been thinned out to from 1 inches to 5 inches apart, this being ample space, as they are always used in a very young state. Spinach we thin out to about the same distance, as large leaves are asked for. The thinnings are not appreciated, though the vegetable is just as good in that young state. The real cause of objection is to be found in the longer time it takes to prepare for table than leaves that are fully grown. We planted out some time ago all the autumn-sown Onions we are likely to require, but a few rows were left as sown to afford supplies as wanted, and it is the remainder of these that have now been thinned out to afford room for those that are to be left to grow to a full size.

RHUBARB AND SEAKALE. The pots, boxes, &c., that have been used on the Rhubarb plot to gently force it on have been cleared away, and a few blanks made good by planting the roots, or portions of them, that were lifted for forcing indoors, after which the ground was lightly forked over, and except hoeing about twice during the summer to keep down weeds, this branch of our work is finished for months to come. From Seakale the ashes placed round the crowns for blanching have been taken away, the flowering shoots cut down, and all but two of the most promising shoots on each crown rubbed off. Only one growth, the strongest, will be permitted to remain on the plants of the newly planted plot, and all others will be rubbed off as soon as discernible. The ground from which our late supplies of Kale have been taken by covering up the crowns with ashes, having had a good dressing of Beeson's manure, is now being deeply dug and as close up to the crowns as it is safe to do it without injuring the roots. Seedlings are just emerging through the soil, and slugs having found them out, the usual antidotes, soot and fresh lime, will be applied forthwith.

BROCCOLI. The final sowing is now made, and profiting by the past two severe winters, the kinds that have stood best are those we have now sown. They are Sutton's Late Queen, Safeguard, Veitch's Model, and Purple Sprouting. Late Queen is the gem of the lot. Purple Sprouting we are now cutting in quantity; this and Cottager's Kale, or as it is sometimes called Asparagus Kale, are now, and have been for some time, our mainstay in the way of green vegetables; though, up to a fortnight ago, Brussels Sprouts made up an excellent trio. The latter are now over, but the two former will, I think, last till the spring Cabbages are in, which we have usually been able to commence cutting by the middle of April; if we could cut by the middle of May this year, but if another week be added they will be no finer than, as a general rule, they are in April.

GENERAL WORK.—To make successional sowings of Lettuce, Radish, Mustard and Cress, the two last-named we put on any bit of spare ground, and from now till end of September sow a little every week. To plant out Tomatoes, we have no wall to give up entirely to them, but a few are planted against any bare bit of the fruit tree walls, and others are planted on a border having a western aspect and well screened from wind. To plant out

Vegetable Marrows on ridges prepared by throwing together all the spare vegetable refuse and manure. When first planted out it is necessary to guard the plants from wind and frost, either by handlights or a thick screen of evergreen branches. To draw soil close up to Potatoes, so long as there is any risk of the haulm being injured by frost, and any that are already too high to be protected in that way we cover with straw or litter whenever there are signs of frost. To make another sowing of Peas, and also of dwarf French Beans, and in dry weather, whenever opportunity offers, hoe between the rows of Carrots, Parsnips, Onions, Peas, and Broad Beans.

W. W.

ORCHIDS.

W. H. GOWER.

THE TRICHOPILIAS.

THIS is a small genus of handsome-flowered Orchids, nearly all of which are natives of

Trichopilias form handsome specimens when cultivated in pots, but the flowers are seen to the best advantage when the plants are grown in hanging baskets. They thrive best in the cool end of the Cattleya house with a genial moist atmosphere and moderate supply of water to their roots during the growing season, but very little is requisite in the winter; yet the supply must not be entirely withheld for any length of time, otherwise the plants will suffer. It is most important that the soil for Trichopilias should be sweet and open and the drainage free, as few Orchids so rapidly decline in health under adverse conditions. In potting these plants they should be well elevated above the rims of the pots or baskets. Thus treated all superfluous moisture rapidly passes away from their delicate roots, and as the flowers are produced below the leaves it affords more space for their display. The potting material should

Trichopilia suavis.

Equatorial America, where they abound in the humid shady forests of that region, for the most part at moderate elevations. They are nearly allied to the Maxillarias, but differ in having long spreading sepals and petals, but more especially in the anther cap, which is curiously ornamented with plume-like tufts of hairs. These plants vary considerably in size, although all of them are dwarf; they are characterised by their compressed pseudo-bulbs, which are enveloped in large and curious sheaths, and bear a solitary thick leathery leaf. The scape is short, bearing one or two flowers (but sometimes several are produced upon a spike), which in nearly all the known kinds are showy.

consist of fibrous peat and living Sphagnum Moss, through which a few nodules of charcoal should be dispersed. Trichopilias are very free bloomers; moderate-sized specimens will frequently produce from fifty to a hundred or more flowers, and these in most instances appear in spring and early summer.

T. SUAVIS, of which we here give an illustration, ranks amongst the largest of the species, and is a fair representation of their general contour; the sepals and petals are creamy white; the funnel-shaped lip is also white stained with yellow in the throat, blotched and spotted with rosy crimson. The flowers yield a grateful perfume resembling that of Hawthorn. The rare

variety *alba* is entirely white, saving a stain of yellow in the throat. It comes from Costa Rica.

T. TORTILIS.—The flowers of this species resemble the previously named kind in shape; the sepals and petals are narrow, spirally twisted, brown in the centre, bordered with yellowish white; lip yellowish white spotted with brown and rose. It comes from Mexico.

T. HYMENANTHA is a distinct plant, with long, narrow, thick, and fleshy leaves, which are pale green on both sides. The raceme is drooping, bearing six to eight flowers; sepals and petals white, slightly twisted; lip nearly flat, white speckled with reddish purple, and toothed round the edge. It is a native of New Grenada.

T. COCCINEA comes from Central America; the sepals are long and spreading, slightly twisted, reddish brown, narrowly bordered with white; the trumpet-shaped lip is white on the outside, reddish purple, shading to crimson in the throat.

T. GALEOTTIANA is a plant with yellowish white sepals and petals; lip deeper yellow, passing into orange in the throat, and freckled with linear markings of reddish crimson. It grows wild upon the snow-capped mountain of Turialva, in Veraguas, but at no great elevation.

T. CRISPA is a fine species of robust growth; the sepals and petals are large and broad, carmine-red, narrowly bordered with white, and undulate on the margins; lip white outside, deeper red within than the petals, shading to dull crimson in the throat, front lobe crisp, and margined with a narrow white border. The variety *marginata* has stouter pseudo-bulbs and broader leaves; the flowers are also larger and much deeper crimson in colour. Both forms come from Costa Rica, where they grow upon trees overhanging streams of water.

T. LEPIDA somewhat resembles the last-named kind in habit and appearance, but its showy flowers are very distinct, and are some 4 inches or 5 inches across; sepals and petals rosy red, with an irregular white border; the trumpet-shaped lip is purplish crimson, becoming deeper in the throat, with a broad irregular white border, spotted and blotched with crimson-purple. In the variety *rosea* the lip is of a bright rose colour in the centre. This species and its variety come from Costa Rica.

Sobralia leucoxantha.—This is an elegant dwarf-growing member of a family too much neglected by Orchid growers; the distinct growth and numerous handsome flowers render these plants conspicuous in a collection of Orchids. The complaint against *Sobralias* is, that the flowers are very fugitive; but to counterbalance this, a great number of blooms issue from each spathe, so that a long succession of flower is maintained. This rare variety grows about 18 inches high, producing flowers between 5 inches and 6 inches across, sepals and petals white, lip white externally, beautifully crisp on the edge, the throat being rich orange and yellow.—G.

Cattleya citrina.—This is considered by some Orchid growers a most difficult plant to flower, but here it seems to thrive. We have one plant at present bearing six beautiful rich yellow wax-like flowers of great substance, the lip being beautifully frilled and edged with white, which contrasts well with the deep yellow. *C. citrina* succeeds best in a cool house in summer, and in a temperature of from 45° to 50° in winter. It requires no soil whatever to grow in, just merely fastened with copper wire to a teak raft or a piece of cork. This drooping habit not only protects the blooms, but adds greatly to their beauty, as it is the only way in which the flower can be seen to perfection. *C. citrina* should be suspended from the roof. When

mounting them on teak rafts, which snit them best, care should be taken to have the bulbs placed downwards. Water freely in the growing season; afterwards withhold the supply.—S. B. G., *Nearbridge*.

Odontoglossum elegans.—This is supposed to be a natural hybrid between *O. cirrhosum* and *O. cristatum*. That the first named is one of the parents there can be little doubt, but, judging from the plant which was recently in bloom at The Woodlands, Streatham, the second parent is very likely *O. Halli*. The flowers are large, the sepals and petals are somewhat narrow, with much the character of those of *O. cirrhosum*, yellowish white blotched with chocolate; lip triangular in shape, toothed on the disc, white in front, with a large bright brown blotch on the centre, with a few spots of the same colour near the apex, crest deep yellow. A coloured plate of this form appeared in THE GARDEN, Vol. XXVI, p. 276. G.

Dendrobium Dalhousianum.—I send you a piece of *D. Dalhousianum*. The plant is 4 feet 6 inches high, carrying seven spikes of flower and was imported from Burmah about four years ago.—G. T. S., *Godstone*.

* * * The inflorescence sent represented a very fine form of this superb species. The flowers measured 4 inches across, the sepals and petals being rich creamy yellow suffused with soft rose colour; lip recurved in front, white, crested all over with short filaments, the basal part being lined with crimson, and bearing on each side a large eye-like spot of bright crimson-purple. The plant is a tall grower; therefore, those with small houses only cannot accommodate it; but where space will admit of its culture it should never be absent from a collection, as no finer species has hitherto been introduced.—Ed.

SHORT NOTES.—ORCHIDS.

Odontoglossum gloriosum.—A very handsome form of this fragrant species is now flowering at Selborne, Streatham, the residence of Mr. J. Southgate. The flowers are large, sepals and petals white, irregularly spotted with chestnut brown. This variety was imported a few years ago under the name of *O. nœvium majus*, but although it is not the latter variety, it is a very distinct and charming plant, and equally as free growing and hardy as the typical *gloriosum*.—G.

Lælia purpurata alba.—I send by parcels post a flower of *Lælia purpurata*, which I shall be much obliged by your informing me through your journal if it be any special variety. It is taken from an imported plant purchased in 1884, and has at the present time sixteen fully-expanded blooms, and has been in flower during the last fortnight.—W. S. Brown.

* * * A very fine form of *Lælia purpurata alba*, the flowers measuring 8 inches across. We have seen varieties in which the sepals were wider, consequently forming a fuller flower.—Ed.

Destruction of wild flowers.—I am much interested in what Mr. Coleman says about the fashion of gathering lovely wild flowers in such quantities, and so carelessly as to destroy them, and not only the flowers, but the woods in which they grow, especially in places like Eastnor Park, where they are only half wild. This is, I truly believe, a mere fashion, for it is hardly possible that real flower-lovers would act so ruthlessly. We are not free from the pest even in this region. In that remarkable geographical formation, the angle between the Loch running up to Fort William and Loch Eil proper, there are several islets; one of these is called the Lily Island, because it is, or, alas! was, nearly covered with single Daffodils. Tradition says they are not really native plants, "that there's no like o' them in the country," but that they came from France to decorate an ancient garden belonging to a castle built on the island by a Lochiel of some remote period. Thus these beautiful flowers have occupied the same spot for centuries, but within the last few years the modern craze for wild flowers has reached Lochaber; people have gone over in boats to the Lily Island, not only gathering the blossoms, but digging up the roots, so that this year no Daffodils were to be found upon a reasonable number were required for the Easter decoration of the Episcopal Church at Fort William. This wanton mischief is more completely

inexcusable than it would otherwise be, because moderate gathering of wild flowers by those who really love them would do no harm; when we gather blossoms from our gardens, we not only abstain from following Mr. Coleman's suggestion as to beating the beds with mats, but are careful not to trample them with our feet; and anybody with right feeling would act in the same way in a Cowslip field or on a Primrose bank.—E. C. M., *Lochalther*.

SOCIETIES AND EXHIBITIONS.

ROYAL HORTICULTURAL.

MAY 10.

THE usual fortnightly meeting of the fruit and floral committees was held in the conservatory, and was rendered very attractive by the groups of Roses, &c., exhibited.

The following first-class certificates were awarded, viz.:—

NARCISSUS CAPTAIN NELSON.—A very handsome variety of the large trumpet section, of a rich golden yellow colour, with lighter petals. Exhibited by Mr. T. S. Ware and Barr and Son.

NARCISSI GLORIA MUNDI, GLORY OF LEYDEN, MADAME W. DE GRAAF.—All of these shown by Messrs. Barr and Son.

PRIMULA SIEBOLDI (Ware's White).—A pure white variety with large flowers. Shown by Mr. T. S. Ware.

FRITILLARIA PALLIDIFLORA.—A variety with pale yellow flowers and a few dark spots. Exhibited by Mr. T. S. Ware.

The most remarkable feature was doubtless the *Cypripediums* staged in competition for the Veitch memorial prize, for which there were two competitors, viz., Mr. R. J. Measures, Cambridge Lodge, Camberwell, and Mr. G. F. Tautz, Studley House, Hammersmith. The group from Mr. Measures was perhaps the finest collection of Lady's Slipper Orchids which has ever been staged in public competition in this country. It consisted of about fifty varieties and double that number of plants. The artistic manner in which the plants were arranged, and their different forms and colours so well contrasted, amply proved that these plants are most effective and ornamental even without the addition of other flowers. The most notable kinds were *C. curvandrums*, *superbiliaris*, *selligerum*, *Robelini*, *Lawrenceanum*, *laxigatum*, *caudatum* in variety, *ciliolare*, *Curtisi*, *cardinale*, *Druryi*, *vernixium*, *Stoneli*, *Argus* in variety, various forms of *barbatum* and *Boxalli*, and numerous others. The plants were arranged in a groundwork of Maiden-hair Ferns and small Palms, so that the pots in which they were growing were completely hidden. This group deservedly received the prize. Mr. Tautz exhibited *C. Lawrenceanum*, *niveum*, *pubescens*, *Peteri*, *Sedeni*, *Lowi*, *Druryi*, *barbatum* in variety, *ciliolare*, *Boxalli*, &c.—in all about a dozen and a half varieties.

Mr. G. Cragg, nurseryman, Crouch End, sent a group of seedling *Auriculas*.

Mr. R. Dean, Ranelagh Road, Ealing, staged a group of *Polyanthus* in several varieties, all very handsome.

From Mr. Miles, nurseryman, Shoreham, came plants of a new Regal *Pelargonium* named Pearl. It appears robust and dwarf in habit and very floriferous, flowers semi-double, pure white, with just a spot or two of carmine. It will no doubt become exceedingly popular for furnishing purposes as well as for cutting from.

Mr. De B. Crawshay, Rosefield, Sevenoaks, exhibited three plants representing as many forms of *Odontoglossum crispum*, all remarkable for size and fullness of flower.

Mr. Shuttleworth, new plant merchant, Clapham Park, sent *Cymbidium tigrinum* and a curious new hybrid *Odontoglossum*, which received the provisional name of *Carderi*. It is very distinct, and will probably prove to be a fine variety with further cultivation.

Mr. G. F. Tautz, Studley House, Hammersmith, sent a small plant of the curious and rare *Odontoglossum Schillerianum*, cut flowers of several varieties of *Cattleya Mendeli*, and *Phalenopsis Sanderiana*.

Mr. Rumsey, Joyning's Nursery, Waltham Cross, sent cut Roses, many of which were of great excellence, particularly a stand of twenty-four blooms of *Souvenir d'un Anni*, which were of a most exquisite tint of rosy peach. Other fine blooms were Madame Jules Margottin, Marie Van Houtte, Amazon, Catherine Marnet, Madame Lambard, Charles Lefebvre, Paul Neyron, *Souvenir d'Elise*, Baroness Rothschild, and *alba rosea*. A bronze Banksian medal was recommended.

A group of *Narcissi* came from Messrs. Barr and Son, King Street, Covent Garden; the blooms were not overcrowded, and being arranged with their own foliage had a very pleasing effect, their appearance at this date clearly indicating the unusually late spring. The group was awarded a silver Banksian medal. Messrs. Collins Bros. and Gabriel, Waterloo Road, were awarded a bronze Banksian medal for a large group of *Narcissi*, &c., these also being tastefully arranged with their natural foliage. Mr. T. S. Ware, Hale Farm Nurseries, staged a large group of *Narcissi* and miscellaneous plants and flowers, for which he was awarded a silver-gilt Banksian medal. Mr. E. H. Krelage, Haarlem, sent a collection of *Tulips* and *Narcissi*.

Mr. A. Waterer, Knap Hill Nurseries, Woking, staged a group of hardy *Azaleas*, consisting of some very fine forms of mollis and numerous plants of *A. pontica narcissiflora*, the flowers of which are soft lemon-yellow, semi-double, and very fragrant; also several plants of *Cydonia japonica Simonsi*, in which the flowers are very large and rich deep crimson in colour.

Mr. J. James, Farnham Royal, Slough, showed flowers of his very fine strain of *Calcicolarias*.

Messrs. Tuchman and Sons, Upper Tooting, sent seedling *Rhododendron javanicum*.

Messrs. W. Paul and Son, Waltham Cross, sent a remarkably fine group of Roses in pots. They consisted of well-grown dwarf plants edged in front with a row of trays of cut bloom; the most notable flowers in the collection were *Magna Charta*, Countess of Rosebery, Duke of Teck, Grace Darling, Madame Falcot, Camoens, Glory of Waltham, Violette Bouyer, La France, Maréchal Niel, Captain Christy, Devonensis, Red Dragon, Alexander Bernaix, Duke of Wellington, Crown Prince, Niphetos, John Hopper, Dr. Andry, and M. Furtado. A silver-gilt Banksian medal was awarded.

Messrs. Pearson and Sons staged a fine lot of cut trusses of single zonal *Pelargoniums* of wonderful size and shape, the best being W. Bealby, rosy scarlet; Rev. R. D. Harris, soft salmon-scarlet; Sissy, salmon, shaded orange and pink; Ruby, rosy scarlet, white eye; Norah, blush white; Mrs. Millar, dark crimson; Mrs. Johnson, rose; International, white, very large; Lady Francis Russell, clear rose-pink; C. H. Swinstead, vermilion; *Aspasia*, white; Edith Pearson, rosy salmon; Mrs. David Saunders, pale lilac-pink; and Lady Chesterfield, salmon, suffused with orange.

Fruit committee.—Mr. Norman, Hatfield House Gardens, sent six remarkably fine bunches of Lady Downes Seedling Grape, which had been ripened in the last week in September, 1886. The berries were as fresh and plump as they were at that time. Black Hamburgs of this season's growth came from Mr. W. F. Hume Dick, Thames Ditton, who also sent a scarlet-flesh Melon called Thames Ditton Hero. This the committee wished to see again. A seedling green-flesh Melon came from Mr. Parker, Impney Gardens, Droitwich, and Mr. Goodacre, The Gardens, Elvaston Castle, Derby, sent a dish of fair-sized Elvaston Long-keeping Onions. From the society's gardens at Chiswick were sent several varieties of Rhubarb.

Scientific Committee.

Peristeria cerina and *P. guttata*.—Mr. O'Brien exhibited two flowers, one yellow the other spotted, believed to have been borne by the same plant, and characteristic of these two species. It was suggested

that they might prove to be male and female respectively. Mr. Ridley undertook to examine and report upon them.

Longicorn beetle in *Saccolabium ericete*.—Mr. Pascoe exhibited a live specimen taken from a stem. It proved to be *Diaxenes Taylori*, from Moulmein, in the Malay Peninsula.

***Leucijum trichophyllum*.**—Rev. C. W. Dod showed a specimen of this plant. Though figured in an early volume of "Curtis's Magazine," it appears to have been lost. It is a native of Portugal.

Daffodils, hybrids.—He also showed a number of native hybrids between *N. poeticus* and *N. pseudo-Narcissus*. They grow in abundance and great variety at an elevation of 7000 feet in the Pyrenees, since as soon as the snow disappears both these species flower simultaneously, and not separately, as in England. They are called "Bernards" in their native home.

Euonymus vars.—Dr. Masters exhibited sprays of the common green *Euonymus* with yellowish young foliage. They were received from M. Max Cornu. The yellow tint disappears as the season advances; the cause was attributed by the secretary to cold, as he had noticed transplanted Bluebells remained yellow-green until the temperature rose, when they suddenly became green. Mr. Murray corroborated this fact, and added that corn will sometimes become yellow again on return of cold weather.

Tulip bulb abnormal.—Dr. Masters also showed bulbs in which one of the lowermost scales had become bent downwards; an axillary bulb had grown downwards in conjunction with it. Mr. Dod alluded to the fact that Bluebells and Crocuses sometimes bore bulbs on dependent axes below the parent bulb; but it was somewhat difficult to account for this peculiarity.

The following communications were received from Mr. Plowright:—

Distorted Crocus leaves.—"The Crocus leaves sent herewith present a curious distorted appearance towards their extremities that I have frequently observed at this season of the year. It usually becomes more marked later on. At first sight one would imagine it due to some mechanical injury, but this I believe not to be the case. The plants from which these specimens are taken have had their leaves similarly distorted for several years in succession. Whether it be the work of an insect or not, I should be glad to have the opinion of any member of the committee who may be familiar with this diseased condition." This is of common occurrence, and is due to chill or other cause which prevents the leaves escaping freely from their sheaths.

Larch disease.—"Most likely several diseases are included in the term 'Larch disease,' as one frequently sees it employed in various semi-scientific periodicals. The specimens in question were obtained last autumn near Aberdeen in one of the excursions of the Scottish Cryptogamic Society. Professor Trail pointed out to me the large number of young Larches which were thus injured. During the following week, while at Hereford, I searched in vain for specimens of this disease, nor have I been more successful with the Larches in this neighbourhood. The specimens sent herewith were living at the time they were procured, the leaves attached to them being quite green. The peculiar swellings of the affected branches being like those produced by the Podosomata on Junipers—more or less fusiform—there is no reasonable doubt but that the disease is caused by the presence of the mycelium of a fungus, *Peziza Willkommii*. The diseased condition of the branches and the structure of the fungus, &c., are well shown in R. Hartig *Lehrbuch der Baumkrankheiten*, pl. xi. The specimens show the fusiform swellings of the branches and the *Peziza Willkommii in situ*. It has been asserted by those who confine their attention to the examination of herbarium species that no difference exists between *P. Willkommii* and *P. calycina*. Without doubt the perfect fungi resemble each other closely in external appearance and in spore measurements, but their life history is distinct, the former affecting living trees, the latter dead ones. A similar case in point occurs with the two acidia,

which in this county occur upon *Ranunculus repens*, the one of which is connected with *Puccinia Magnusiana* on Reed and the other with *Uromyces pop.* For my own part, I am quite unable to distinguish these acidia from one another, either by their external appearance or by their spore measurements, but their life history is abundantly distinct." It was the opinion of Mr. Smith and Mr. Murray that *Peziza*, a purely superficial fungus, had nothing to do with disease, but only followed it.

Cymbidium tigrinum.—A finely grown specimen of this plant was exhibited by Messrs. Shuttleworth, Carder and Co., Clapham. It was figured in *Botanical Magazine*, t. 5457. A botanical certificate was awarded for it.

Arisema triphyllum.—A North American Aroid, green var., was exhibited by Mr. Ridley; the usual form is more showy, having purple spathe with bars.

***Dracunculus creticus* (Schott).**—This powerfully odoriferous Aroid from Crete was shown by Mr. Lynch, who observed that it proved to be perfectly hardy during the last two winters.

Sisyrinchium filifolium, from the Falkland Islands; *Iris lineata* (Foster), from the Caucasus; *Arctotis aureola*, *A. revoluta*, and *A. arborescens* were shown by Mr. Lynch.

Narcissus committee.—The last meeting of the committee for this season was held at South Kensington, on Tuesday, May 10. Among the specimens received were a seedling from Emperor, registered as Glory of Leyden, a seedling from Empress-moschatus, registered as Madame de Graaff, and a variety of tridynamis, which the committee desired to see again; all from M. de Graaff. Tridynamis, raised by Mr. Rawson, registered as A. Rawson. From Dr. Wallace, a citron-coloured double form of incomparabilis, with the corona entirely suppressed, similar to what appears sometimes as a sport in sulphureus plenus. It was doubted whether it would prove constant. In some cases only half the flower sports in this manner. Mr. Ware showed a flower similar to the above, together with a single form, which had been cut from the same bulb of the variety known as semiparviflorus. Mr. Barr sent a flower observed among collected bulbs of moschatus in which three of the anthers and stamens on one side were beginning to form a double flower. A natural hybrid, a variety of N. Bernardi, was registered as H. P. Buxton; and Mr. Barr also showed a collection of triandrus illustrating the great variation in form. It was thought desirable to register the variety which had been known as Burbedged conspicuous under the name Constance, in order to avoid the confusion which might occur between it and the variety of Barri called conspicuous, as also in order to carry out the principle of naming all garden forms and hybrids in the manner adopted by florists, and not in the manner adopted by botanists. — C. R. SCRASE-DICKINS, *Hon. Sec.*

SHORT NOTES—VARIOUS.

Scottish Pansy Society.—We note that the date of this society's exhibition has been altered from the 17th to the 24th of June, on account of the Jubilee holiday.

Chrysanthemum show and conference.—The council of the Royal Horticultural Society have resolved not to hold the proposed Chrysanthemum show and conference which had been fixed for November 8 and 9 next.

Dresden International Horticultural Exhibition.—At this show, which opened on the 7th inst., Mr. B. S. Williams, of the Victoria and Paradise Nurseries, Upper Holloway, was awarded two gold medals and prize of honour for collection of Orchids, new and rare plants, Cyclamens, Anagallis, Hiansophyllums, "The Orchid Album," and his various other horticultural works.

Basic slag.—"F. H." can get basic slag from Mr. S. M. Thomson, manure manufacturer, Lamark, by steamer from Glasgow to Liverpool.—M. G.

Mushrooms.—Can you tell me the enclosed is? Is it a Mushroom or a fungus? It comes up in my Mushroom beds, but I am afraid to use it.—M. C.

The Mushroom sent is a perfectly genuine one, but it belongs to a peculiar and perhaps inferior variety. It must not be assumed that inferior Mushrooms always arise from inferior spawn. Good spawn under bad conditions of growth will give rise to inferior Mushrooms. Our correspondent's example is 8 inches across, dark sooty brown in colour on

the top, rather thin in the flesh (for so large a specimen), and with a comparatively thin and lanky stem. A very distinct form.—W. G. S.

LAW.

ACTION AGAINST A TENANT FOR CUTTING DOWN SHRUBS.

THE action (Smith v. Oliver) was brought to recover damages for waste caused by the defendant in cutting down trees and shrubs on the grounds of the plaintiff. The defendant denied the damage. The plaintiff is an accountant and agent at Warrington. About ten years ago he bought what was described as a "charming little place" called Bryn y Gwynt, at Pant Asaph, Flintshire. The house and grounds were subsequently let to the defendant, at a rental of £30 per year, and during his tenancy the trees and shrubs were cut down. The place, which was formerly admired for the beauty of its Evergreens, had been, it was alleged, denuded of its most beautiful feature, and its letting value was therefore reduced. Several landscape gardeners gave evidence, and expressed the opinion that the value of the house and grounds had been reduced by £250 to £300 through the cutting down of the trees. The plaintiff said he let the house to the defendant at a reduced rental on the understanding that he would trim the grounds. The Judge said there were several ways of trimming grounds, as one man might trim a garden by keeping up the trees in a particular way, and another man might trim it by letting in sun and air. Mr. Collins contended that none of the trees had been cut down to the stumps. The house was damp, and what the defendant did was with the view of letting in light and air. Mr. Johnson, manager to Messrs. Dickson & Sons, nurserymen, Chester, and other witnesses, gave evidence to the effect that the way in which the trees had been pruned and cut improved their condition. In summing up, the Judge said the evidence of Mr. Johnson and the other witnesses for the defendant was entitled to much weight. In his opinion there was not the slightest pretence for the large claim the plaintiff had made. The jury returned a verdict for the defendant.

Death of Mr. G. Ford.—We are sorry to hear of the death of Mr. G. Ford, who had for many years been gardener to Earl Cowper at Wrest Park, Bedfordshire.

G. S.* Specimen insufficient, kindly send flowers.—*Kent.*—Yellow flower *Oncidium sessile*; small dotted flower *Restrepia elegans*; other flower *Miltonia*, name next week.—*B. Sell, Worthing.*—You will find a notice of the Pelargonium in report of Kensington show of this week.

Names of fruits.—*T. T.*—The small fruit is *Burré Rouge*; the other, *Burré Gris d'Hiver*.

WOODS & FORESTS.

“YORKSHIREMAN.”

FORESTRY NOTES.

SHRUBS FOR THE SEASIDE.—Judging from the very limited number of shrubs that is usually seen in maritime gardens, one is led to believe that few indeed are the members of such that will succeed under these conditions. This is, however, quite a mistake, as from rather long experience in a seaside district we have found out that the number of both trees and shrubs is by no means meagre, and includes some of our most ornamental-foliaged and flowering subjects. The Escallonias are particularly well adapted for planting in seaside gardens, and grow with a luxuriance there that it is unusual to see even in warm inland situations. Two or three kinds of Myrtle may in many of the maritime Carnarvonshire gardens be seen flourishing to such an extent that dwellers in inland districts feel vexed that they cannot imitate them. Then, again, we have the tree Purslane (*Atriplex Halimus*), the *Coluteas*, Box Thorn (*Lycium europæum*), Lilaes of sorts, the Tree Groundsel (*Baccharis halimifolia*), the pretty-berried, silvery-foliaged Sea Buckthorn, *Fabiana imbricata*, the *Pittosporums*, *Aloysia citriodora*, or the lemon-scented *Verbena*, and hosts of other shrubs that time and space will not permit of our mentioning at present. Amongst trees particular mention may be made of the *Sycamore* and *Willow*, the *Aleppo Pine* (*Pinus halepensis*), *Pinus Pinaster*, and *Cupressus macrocarpa*. The list might be greatly extended, and will be perhaps in an article devoted to the most suitable trees and shrubs for planting along the sea coast.

FILLING UP GAPS IN LIVE FENCES.—This is an operation that rarely receives the amount of attention it deserves, for when attended to in time and properly executed it is productive of very great good by maintaining the hedges in a sound and perfect condition. From many causes woodland live fences are apt to get gappy and broken, and which, if not attended to in time and the work well performed, soon tell a tale and necessitate extra expenses in many ways. Where *Quicks* are to be substituted for such as have died out, only those of strong growth and with plenty of bushy roots should be used. It is well also to take out the old and exhausted soil from the line of fence, and substitute instead that of good quality from an adjoining field or wood. Great care is necessary in digging out or grubbing up the dead plants to avoid as much as possible cutting or maiming of the roots of the adjoining live *Quicks*, but this is easily enough avoided by carefully picking out the soil and well loosening it up before using the spade. A few poles materially assist in strengthening such newly filled-up gaps until such time as the *Quicks* have become strong and established. It is always advisable to have a few extra strong picked plants of the *Quick*, *Beech*, *Hornbeam*, or *Privet* set aside in the home nursery for filling up such gaps in woodland fences.

TREE GUARDS.—These should always be erected of sufficient height to prevent horses and cattle, the former in particular, barking the stems and browsing on the branches of valuable trees and shrubs. For trees whose stems are destitute of branches for 10 feet or so from the ground, all that is necessary is to nail uprightly small poles to a circular hoop placed around the tree's stem at 6 feet from ground level, the ends of the poles being driven into the soil for half a foot. The hoop should not be placed too tightly around the tree's stem, and the points

of the upright poles which project above this may be sharply pointed, thus preventing to a great extent horses reaching over to bark the stem and branches. Ordinary wire netting has also been recommended for preventing horses, &c., from gnawing the bark of standard specimen trees; but here, at least, this method of prevention has not met with much encouragement. The netting, from its rough surface, acts as a capital rubbing-post when in conjunction with the stem of the tree, and is thus apt to get torn off; while it is dangerous, from the horses' shoes getting entangled in the meshes.

PROTECTING SMALL PLANTS FROM FROST.—Seedling forest stuff that has been transplanted from the seed beds during the past season will require a certain amount of protection during frosty weather, for as everyone who is acquainted with nursery work knows that very considerable damage is often inflicted on young stock by their being lifted bodily from the soil during severe winter weather. We have found the flat branches of *Spruce Fir* or those of *Abies Douglasi* to have a wonderful effect in preserving the young plants against damage; indeed, even during the most intense frost a double layer of these branches will preserve even half-hardy subjects. The branches may be laid flat on the beds in the case of seedlings, or pegged down between the lines of plants in the borders, while as a screen for newly planted out, half-hardy *Conifers* they may be warped out and in between the bars of hurdles, and these placed around the trees to be protected. Until thoroughly established, or as it were acclimatised to the situation, the finer *Azaleas*, *Rhododendrons*, &c., will be all the better for such a screen placed on the windward side of the beds or brakes. During fine, open weather it is advisable to remove the branch covering from seed beds, as owing to the branches being placed flat and excluding the light the foliage is apt to suffer in consequence.

STAKING NEWLY-PLANTED TREES.—Where trees of large size are planted out firm staking should be set about at once. This is rarely necessary in trees of less size than say 6 feet, unless, indeed, the situation be very exposed and the plants used bushy in proportion to their height, when those of from 4 feet upwards may likewise receive attention. Too often it happens that specimen trees are planted out and allowed to rock about with the wind until the roots become so maimed and barked as to be totally unfitted for their proper functions, the result of which is premature decay of the tree. Staking is so simple and inexpensive a matter that in all cases where there is the least likelihood of the trees being root-shaken it should receive early and careful attention, and if well done at the first will require but little after attention. A. D. WEBSTER.

Mismanaged planting.—I was much amused in reading “Yorkshireman's” remarks in THE GARDEN, May 7 (p. 41), in reference to planting, and I think some of his remarks are far from complimentary regarding some of our public nurseries, and more especially to the management of the *Corsican Pine*. I am fully convinced that where “Yorkshireman” has planted one *Corsican Fir* the writer has planted ten, and I may say the same with all other plants. “Yorkshireman” says frequent transplanting is not worth anything if the roots are not there. I always thought that frequent transplanting was the means and object of getting roots. I hold that the *Corsican Fir* will die off in most cases no matter when or how careful the operation of planting is performed. I have planted thousands of them both from home and public nurseries, and always had losses, and I am sure that most planters of the same trees will be able to bear me out in what I say. Talk of planting

in September; in nine cases out of ten most foresters can hardly go into the woods or moors at that season on account of the game. Then as to the notch or slit system of planting, “Yorkshireman” must not have had much experience of this plan, as only on the score of cheapness can he recommend it a very great object in forming plantations, I hold. But after thirty years' experience in the management of woods, the writer could show “Yorkshireman” hundreds of acres covered with fine healthy trees of *Austrian*, *Corsican*, and *Scotch Pine*, and all planted on the notch or slit system. And as to his theory of all forest trees having tap roots, I must say that it is quite new to me. I will close by asking, Did he ever see a *Spruce Fir* with a tap root? RUSTICUS.

Abies Douglasi at Jardine Hall, Dumfriesshire.—This tree, figured in Solby's “Forest Trees,” was planted in 1828 as a seedling 2 feet high, and is therefore of the same age as that at Dropmore.

Year.	Height.	Girth at				Diameter of spread of branches.	Circumference of spread of branches.
		base.	1 foot.	3 feet.	5 feet.		
1828	F. 2.	—	—	—	—	—	—
1842	25	—	2	9	—	—	14
1845	—	—	3	7	—	—	—
1875	—	—	11	0	—	6	—
1881	—	—	12	0	10	3	55
1884	—	13	0	12	7	11	0
1887	70	—	—	—	—	11	0

Owing to crows building as this year for the last thirty or forty years, the top is much broken, and, instead of 70 feet high, might have been 105 feet or even more.—W. H. MAXWELL.

Creosoting timber.—It has been said that no process of treating wood by chemicals to make it durable had proved a success. From 1838 to 1853 four processes were in active competition for public favour. Creosote proved, after fifteen years' experience, most reliable and stable. About this time the construction of railways in India commenced, but it was soon discovered that the native timber was subject to rapid destruction by decay, and the East India Railway Company were forced to provide durable material for their permanent way. They accordingly sent out large quantities of creosoted sleepers, and after an experience of sixteen years, pronounced decidedly in favour of this process. The intensely acrid and pungent properties of acridine present in the creosote proved destructive to all insect life. In 1848 Mr. Bethell creosoted the telegraph poles for a line from Forcham to Portsmouth, a distance of twenty miles. In 1874 the requirements of the service necessitated the removal of these poles, and when taken down they were found as sound as when first erected in 1848, twenty-six years. In 1859 the managers of the railway company's line from Rouen to Dieppe, in France, creosoted their sleepers. Twenty years later an examination on the occasion of the Paris Exhibition showed that not a single sleeper bore the slightest trace of decay.—J. F., in *Country Gentleman*.

Pines as medicinal agents.—Although some forests are regarded as sources of malaria, and Oak trees and Hazel bushes have been counted insalubrious in Europe, like the Tamarind tree in the East, yet the air of Pine forests appears always grateful to the lungs, and has been considered wholesome, although of its absolute curative influence there is little evidence, and, indeed, it must be difficult to procure such. The idea of Pine forests exercising a balmy influence on the lungs is a very ancient one. Pliny considered that the air of Pine forests was more useful in phthisis and in convalescence from acute diseases than the voyage to Egypt recommended in such cases in those days. Both Bourneouth and Arcachon at the present day owe a good deal of their reputation to their Pine woods. The air of the latter is said to be distinctly

sedative. On the whole, then, the air of the Pine woods of the Black Forest may be regarded as an element entering into the consideration of the value of its baths. But besides merely inhaling the air of its forests, people have of late years made much use of the products of Pine in baths, vapour baths, and inhalations. Even this is not entirely modern, for the ancients recommended chiefly the internal use of decoctions of Strobili and of Pine tops, and thought Pine nuts very useful in diseases of the chest; and at a more modern time, besides the internal use of drinks made from the Spruce and the far-water so long in vogue, we had inhalations of tar and of various resins. The ancients did, indeed, recommend in gout baths of water in which Cedar wood had been boiled, but the use of the Pine extract bath is quite modern. It has spread rapidly, and is in use at Gleisweiler, Rehburg, Liebenstein, Ruhla, and Eisenach. These aromatic extracts are procured from various Pines—as from the *Abies excelsa* or Norway Spruce, Silver Fir, *Pinus sylvestris* or Scotch Fir, *Pinus maritima* or Bordeaux Pine, the Weymouth Pine; also from the common Larch, and the most fragrant of all, from *P. Pumilio*, the Mountain Pine. The baths vary considerably in strength and in odour, according to the way in which they are prepared. The commonest way of making the bath is by adding to common water a certain quantity of the decoction got by passing steam through the young Pine tops.

TREE PLANTING ON A SMALL SCALE.

THE planter of trees on a small scale necessarily needs a greater variety of trees than one who plants extensively; and in the formation of plantations it may be as well to point out that, for the sake of immediate effect, there are various trees which may be employed that grow tolerably well for a few years, during their infancy and youth, upon soils that are not strictly appropriate for their full development. These will produce an immediate effect and clothe an otherwise bare situation. Handsome residences are often seen standing upon bare sites, unaccompanied by the necessary finish and adornment that tree growth alone can confer. Although suitability of soil should always be first considered with respect to the trees that are intended to stand permanently, yet by having recourse to a few quick-growing ones, the desired change can be very much hastened. With this end in view, the Poplar tribe will be found very useful, even if planted with the object of their being cut down when the more highly-prized but slower-growing trees have attained sufficient size. Of these Poplars, the Black Italian (*Populus monilifera*), or Necklace-bearing Poplar, as it is sometimes called, is one of the most rapid in growth; the Grey Poplar, too (*P. canescens*), attains a considerable size in a comparatively brief space of time, as will also the Canadian Poplar (*P. canadensis*). This latter will attain a height of 50 feet in twenty years, and will not only be high, but be furnished with a proportionate amount of branches. The White and Bedford Willows might also be associated with the Poplars. These Poplars are by no means favourites with many people, but their tall graceful shape serves as an excellent contrast to round-headed trees of a different habit of growth.

The fastest-growing trees are the Willow, Poplar, Alder, Horse Chestnut, and Lime; and these thrive best in moist land or near to water, but if the soil is deeply trenched, they will maintain a fair growth for some years, even on sandy uplands more adapted for coniferous trees. Upon good land, that is neither on an elevated situation nor in a low-lying district, surcharged with moisture, the broad-leaved trees, such as Ash, Oak, Elm, Beech, Birch, Plane, Hornbeam, Locust, Walnut, Sycamore, Spanish Chestnut, &c., succeed perfectly. Where the soil is thin and poor, and especially in cold and somewhat elevated districts, Conifers, such as the Stone Pine, Scotch Pine, Silver Fir, Larch, and Cedar, are the most appropriate trees; and to these may be added Spruce Fir, which succeeds best upon the lower slopes, where a greater share of moisture is to be obtained than in higher situations. Many of the Coniferae of comparatively recent introduction into Britain from North-west America, such as *Abies*

Douglasi, *A. amabilis*, *A. grandis*, *A. nobilis*, *Pinus Lambertiana*, and others, though planted during the first quarter of the present century, cannot even now afford examples of what they will become as timber trees in this country.

In ornamental planting on a small scale much may be done to produce a diversified effect by making choice of those trees possessing a varied and distinct appearance at different times of the year. For example, Lilies and Laburnums, Thorns (scarlet and common), and the Horse Chestnut have a beautiful effect in early spring, while the berries of others, such as the Mountain Ash, Cotoneasters, Thorns, and a host of others, produce quite an ornamental effect in autumn. The decaying foliage, too, of others in the autumn changes to deep yellows and glowing reds, such as the various American Oaks, Maples, Liquidambars, and Tulip trees, and produces some brilliant effects, particularly when the first frosts have tinted the foliage of most other deciduous trees.

In all ornamental planting evergreen shrubs should form an important part, and in skilful grouping these should be made to associate harmoniously with the deciduous kinds. Among deciduous trees of small stature, besides those mentioned, the Almond, Hazel, Cherry, Spindle tree, Willow, Service tree, Apple, &c., should be included, while in spaces where larger-sized trees can be used, the common and purple Beech, Horse Chestnut, Lime, and the varieties of the British Oak, as well as the American Oak, should have a place. Under the shade and drip of trees may be planted the Holly, Yew, and Privet.

A good deal of difference of opinion has been expressed at various times as to the best period of the year for transplanting evergreen shrubs of the kinds I have named, and this divergence, in my opinion, has arisen from different circumstances in those cases which have been cited, when the facts or results have been at variance. Without doubt, September is the best time to transplant Evergreens if they are to be removed only a short distance and the proper precautions are taken, as, at this time, the plant is not quite in a dormant condition, and the roots should not be allowed to get dry. For if the plant is quickly removed to the place where it is destined to stand, it will immediately throw out small rootlets, which will very materially help its future progress. If, on the other hand, the plants have to be packed, and are sent by rail a long distance, which is very often the case with those who purchase of a nurseryman, celebrated, perhaps, for some special kinds of Evergreens, winter or early spring would be the best time; but even in that case they will thrive better if they have been removed in the previous September with a view to preparing them for their final change. Frequent transplanting previous to removal is of great importance to young trees, a principle that is well understood in tree nurseries. W. H. A.

Forestry in Sweden.—The importance of forestry in Sweden, both from a financial and commercial point of view, is now fully appreciated, and the Swedish government seems to be particularly interested in the matter. According to a notice issued some time ago by the Department of Royal Domains, the services of forest engineers can, in general, be obtained gratis from the beginning of the year 1884. It is stated in the notice mentioned that means having been provided for paying forest engineers for the services of private owners of forests, notice is hereby given that either owners or occupiers of forests, or of such land as is suitable for being turned into forest, as well as agricultural societies and communal districts, can obtain the services of such officials in the laying out and arranging of forest culture, and for the necessary thinning of trees and the clearing away of natural underwood, as well as for the drawing up of plans for the methodical cultivation of trees, and to give advice and information in what concerns forest management. Those who wish for help from forest engineers must send written notice to the governor of the province, or to the Department of Royal Domains, together with a statement of the purpose

for which the service is asked, as also the place and the nearest hotel and railway station, and also for how many days the service is likely to be required. Blank forms of application may be had from the Department of Royal Domains from the governors of provinces, from agricultural societies, or from forest engineers. No expenses are to be paid by the applicant except for board during the time of the work, which is to be reckoned at five crowns a day, and payment according to a fixed rate of charges for maps and forest plans, which could not be made on the spot, but which the applicant may wish to have completed afterwards. As many of the agricultural societies of the kingdom have undertaken to pay the daily charge of five crowns on behalf of the applicants in their respective provinces, the services of forest engineers can generally be had entirely gratis.

TREES IN ASSEMBLAGES.

SOME trees possess but little interest unless they are grouped in masses of greater or less extent. A solitary Fir or Spruce, for example, when standing in an enclosure or by the roadside, is a stiff and disagreeable object; but a deep forest of Firs is not surpassed in grandeur by one of any other species. These trees must be massed in extensive groups to affect us agreeably; while the Elm, the Oak, and other wide-spreading trees are grand objects of sight when standing alone, or in any other situation. Groves, fragments of forest, and inferior groups only are particularly interesting in a landscape. An unbroken forest of wide extent makes but a dreary picture, on account of its gloomy uniformity. Hence the primitive state of the earth, before it was modified by human hands, must have been sadly wanting in those romantic features that render a scene the most attractive. Nature must be combined with art, however simple and rude, and associated with human life, to become deeply affecting to the imagination. But it is not necessary that the artificial objects of a landscape should be of a grand historical description to produce these agreeable effects; humble objects, indeed, are the most consonant with Nature's sublime aspects, because they manifest no seeming endeavour to rival them. In the deep solitary woods, the sight of a woodman's hut in a clearing, of a farmer's cottage, or of a mere sheepfold immediately awakens a tender interest, and enlivens the scene with a tinge of romance. Immense forests still overspread a great part of Northern Russia, through which it has been asserted that a squirrel might traverse hundreds of miles, without touching the ground, by leaping from tree to tree. Since the general adoption of railroad travelling, however, great ravages have been made in these forests, and not many years will be required to reduce them to fragments. In the south of Europe, a great part of the territory is barren of woods, and the climate has suffered from this cause, which has diminished the bulk of the streams and increased the severity of droughts. But Nature has established a partial remedy for the evil arising from the imprudent destruction of forests, in lofty and precipitous mountains, that serve not only to perpetuate moisture for the supply of rain to the neighbouring countries, but contribute also to preserve the timber in their inaccessible ravines. Were it not for this safeguard of mountains, the south of Europe would ere this have become a desert, from the destruction of its forests, like the Sahara, whose barrenness was anciently produced by the same cause. Most of the territory of North America is still comparatively a wilderness; but in the United States the forests have been so extensively invaded, that they seldom exhibit any distinct outlines, and few of them possess the character of unique assemblages. They are but scattered fragments of the original forest, through which the settlers have made their irregular progress from east to west, diversifying it with roads, farms, and villages. The recent clearings are palisaded by tall trees, exhibiting a naked outline of skeleton timber, without any attractions. Travelling in a forest, though delightful as an occasional recreation, is, when continued many hours in succession, unless one be engaged in scientific researches, very monotonous and wearisome.

No. 809. SATURDAY, May 21, 1887. Vol. XXXI.

"This is an Art
Which does mend Nature: change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

ROSE GARDEN.

T. W. GIRDLESTONE.

SELECTED NEW ROSES.

THE report of the National Rose Society, which has just been issued, contains on page 34 a list of Roses recommended by the committee for inclusion in the society's illustrated catalogue of select varieties. The list is not a long one, being made up of five Hybrid Perpetuals and five Teas; but this is only natural, as one great object of the society in publishing its catalogue is to protect its members, so to speak, from the flood of worthless varieties in cultivation, by recommending only what is first-rate in each section. The one way in which this object can be effectually attained is by deferring judgment until the verdict of a considerable number of skilful growers has been returned in favour of a new variety after two or three seasons' cultivation, for it is generally two, and sometimes three years before the true character of a new Rose is known. Consequently, it is impossible that a thoroughly reliable list should contain the names of Roses of more recent introduction than two years before the date of publication, and it may be observed that the edition of the National Rose Society's catalogue published in 1884 contains the name of no Rose introduced subsequently to 1882. The varieties now recommended include for similar reasons none introduced since 1884, not necessarily on account of the lack of first-rate novelties among those distributed during the two following years, but simply because growers have not yet cultivated these more recent Roses sufficiently long to be able to express a confident opinion as to their merits.

Of the ten varieties enumerated, it is satisfactory to notice that no less than four are of English origin, Mr. Bennett, of Shepperton, heading the list with that number, while Guillot contributes two, and Lacharme, Levet, Margottin, and Ducher have each provided one; and as the list in the report consists merely of the names of the varieties, it may perhaps be of interest to note a few particulars about these Roses which the committee of the National Rose Society are disposed to consider worthy of inclusion in the front rank.

Of the five Hybrid Perpetuals, Alfred Dumesnil (Margottin) was first sent out from France in 1879, but does not appear to have been generally purchased by the English nurserymen, so that it was not very widely distributed in this country the following spring. Consequently, but little was heard of it until the blooms shown by the few firms that had it, attracted attention, and it was thus quite two seasons late in getting known. At most of the leading Rose shows, however, during the last three years it has been well exhibited by the principal nurserymen, who are unanimous in recommending it; and, considering its somewhat disadvantageous start, it speaks well for its good qualities, that it should have stood sixty-fifth in the list of one hundred varieties that were most frequently exhibited in winning stands during the eight years from 1877 to 1884 inclusive. In habit the variety is not unlike Marquise de Castellane,

having robust, thorny wood: the flowers are large, with a fine deep petal, of a rich carmine colour, almost crimson, and they are very constant and freely produced both in summer and autumn.

Alphonse Soupert (Lacharme) was sent from France in the autumn of 1883, and consequently distributed as a new Rose in England during the spring of 1884. The habit of this plant also is inclined to be robust, though freer and taller-growing than the Castellane type; the flowers are very large, and of a deep, full rose colour, very freely produced, and very effective on the plant. The variety makes an excellent pot Rose, forcing admirably, and in May, 1885, it received a first-class certificate from the Royal Horticultural Society.

The year 1882 witnessed the distribution of several first-rate novelties, including Bennett's two Hybrid Perpetuals, Heinrich Schultheis and Lady Mary Fitzwilliam. The first is a vigorous-growing variety, producing very large flowers of a pleasing fresh rose colour, and quite distinct from anything else. As early as 1884 it had attained the position of eighty-sixth in the list of the hundred Hybrid Perpetuals most successfully exhibited during that year, while last season (1886) it appeared as twenty-ninth in the list of the sixty-nine Hybrid Perpetuals that were most frequently staged on the winning stands at the South Kensington exhibition of the National Rose Society. Heinrich Schultheis is a very fragrant Rose and perpetual, though the autumn blooms are often not very characteristic.

Lady Mary Fitzwilliam is a magnificent Rose, and were it only a little more vigorous it might fairly be described as the finest Rose—*bar Maréchal Niel*—in cultivation. It is certainly the finest Rose of its colour, surpassing both in form and size Captain Christy, Duchesse de Vallombrosa, and similar light-coloured Hybrid Perpetuals. Its habit of growth is of the Victor Verdier type, but rather more thorny, and though the growth is not very free, yet every shoot carries bloom both summer and autumn, and, practically, every bloom is fit for exhibition. When at its best it is the perfection of form, with a high pointed centre, surrounded by large petals almost white at their edges and shading to a rosy flesh at the base of the flower. Ninety-sixth in the 1884 list above referred to, Lady Mary Fitzwilliam last season came out ninth of the sixty-nine Hybrid Perpetuals staged on winning stands at South Kensington, being thus handsomely included among the twelve Hybrid Perpetuals most highly esteemed by exhibitors, while a bloom of it on one occasion certainly, if not more, was selected as the best Hybrid Perpetual in the show.

Rosieriste Jacobs (Ducher) arrived from France in the winter of 1880, to be distributed in this country during the spring of 1881. It is a useful and reliable dark crimson-shaded Rose of good size between Horace Vernet and Duke of Wellington, the latter of which it resembles a good deal in habit; the flowers are carried erect, are very constant, and very freely produced both in summer and autumn, the autumnal blooms being especially valuable on account of their brightness and good quality. In 1886 there were as many blooms of it on winning stands at South Kensington as of such established favourites as Duchess of Bedford, Duke of Teck, M^{de}. Victor Verdier, and Pride of Waltham; and in Mr. T. B. Hall's list of the hundred Hybrid Perpetuals which had afforded him most blooms for exhibition during the two seasons of 1884 and 1885 Rosieriste Jacobs stands thirty-eighth.

Coming now to the Tea-scented varieties, the list is headed by the most recent of all the selected ten, but at the same time one of the most charmingly attractive Roses yet raised, namely, Grace Darling (Bennett, 1884). This variety is fairly vigorous and hardy, having passed through the recent winter with but little harm; it is a most continuous bloomer, and it is thoroughly distinct. The flowers are of good size, and, if necessary, can be grown very large; in colour they are a most delicious mixture of lemon and rosy peach, and whether in the cut state or on the plant, whether in bud or expanded, whether grown on dwarf plants or on standards, are sure to please.

Hon. Edith Gifford (Guillot) came from France in the autumn of 1882, and was distributed here during the following spring. It is pretty hardy, and grows well, and as the upright thorny shoots carry the blooms erect, it is about the most useful and effective white Tea out of doors. It has been likened to *Devoniensis*, but it is much better in all ways, being freer, fuller, deeper, and with a far finer petal than *Devoniensis*. Guillot's other contribution, M^{de}. de Watteville, first sent out in 1883, is also a beautiful Rose. The white lemon-tinted petals, margined and washed on the outer side with tender rose colour, constitute a very distinct and charming flower of good size, and with a high-pointed centre. Both in 1885 and 1886 a box of this variety carried off the first prize for twelve blooms of any new Rose at South Kensington, and throughout the whole of last season beautiful examples of M^{de}. de Watteville were conspicuous at most of the principal shows.

Princess of Wales (Bennett, 1882) is a good Tea, not quite as vigorous as might be wished, perhaps, but not so slender-growing but what it can produce very fine flowers, in form not unlike Comtesse de Nadailac. In colour they are somewhat rosy-yellow on the outside with a richer yellow centre. This variety and the two preceding may all three be considered to rank among the best twenty-four Teas for exhibition, according to the record of the South Kensington Rose Show in 1886, for in the list of the thirty-three Teas and Noisettes most frequently staged in winning boxes on that occasion, Hon. Edith Gifford comes out eighteenth, Princess of Wales twenty-first, and Madame de Watteville twenty-fourth, a fact worth remembering now that there are classes arranged for twenty-four Teas or Noisettes, distinct.

Last of all comes the crimson Souvenir de Thérèse Levet (Levet), sent from France in the autumn of 1882, the only red Tea which is not either almost a pure China, or else disfigured by an underlying tint of dingy purplish colour. This very distinct and striking Rose has been well described as a dark red Niphotos, and it will not be easy to suggest anything that will give a better idea of its appearance. It is very free-flowering, both early and late, and blooms of large size are obtainable; while the plants have stood the recent severe winter very creditably.

Such, then, are the varieties now recommended for admission among the very select, and if, on the one hand, it be wondered that, of all the myriad novelties offered, only ten are found worthy of inclusion among the very best, yet, on the other, it is at any rate a matter for congratulation that of the Roses selected, nearly half should be varieties of English origin.

Rose Camoens.—In their extensive group of Roses at South Kensington, on the 10th inst., Messrs. W. Paul exhibited a bunch of this charming variety, which deserves to be largely grown wherever cut

Roses are in demand. The flowers are of a bright pure rose colour—that rose colour which has a yellow rather than a blue tint for its base—and they are produced perfectly true in colour and character under glass. Considering how good and free a pot Rose Camoens is, one would have expected to hear of its extensive employment in America, where these hybrids, whose character has been strongly influenced by a Tea-scented progenitor, are highly esteemed for the production of cut flowers under glass. For bouquets and button-holes, there are few Roses more popular with ladies than Camoens.—T. W. G.

ROSE PROSPECTS.

Rose prospects, on the whole, are good, in some places even brilliant. Without doubt, the long lasting winter, from December to May—and even May was ushered in in East Anglia with 7° of frost—has hit some Roses hard, and blighted some fair prospects among insufficiently-protected Teas and other choice Roses hitting cut-backs and dormant buds with almost equal impartiality. But, on the whole, the Roses have passed through the ordeal of unusual length rather than abnormal severity well, and there is a promise of a brilliant, though late, Rose harvest.

Seldom have Teas on walls looked more vigorous and healthy. Indoors, mildew has abounded, but out of doors all is clean as well as vigorous. In the open there is hardly sufficient foliage yet developed to form a nucleus for mildew; but this cannot be said of Roses on walls, which are growing freely, and are without spot or stain as yet.

A few new Roses, such as the Bennett, Lady Mary Fitzwilliam, and Her Majesty, have suffered severely from the cold, as well as the old favourite Lamarque, but apart from these the rank and file have wintered well. Unprotected or partially protected Teas have also been frozen back nearly to the root-stocks; but this is hardly an evil to Teas on their own roots, as they all ought to be out of doors and in. This last is a sweeping assertion, which experience justifies, as it has broadened and widened with years. A fig for the old tops of Teas in the open so long as the root-stock is safe and sound. The case is widely different on walls, as one of the chief reasons for growing Teas on walls is to get them into bloom in May or very early in June to fill up the blank that is apt to occur, where wall Roses are absent, between Roses under glass and Roses in the open. The old wood of Teas on walls will be in and out of bloom before the young shoots that burst forth from the root-stocks are showing their first buds; hence the importance of conserving the old shoots of Teas on walls to ensure an early and intermediate Rose harvest, that links together that of Roses under glass and in the open. We want a few more Roses in the style of *Maréchal Niel* and of various colours to add to the variety and ensure a more abundant harvest through the intermediate season.

At present the *Maréchal Niel* and the *Gloire de Dijon* are almost the only Roses of any substance that can be relied on from warm walls in the open through May. Safrano of both varieties, the common apricot-yellow and the so-called red, and *Isabella Sprunt* also form useful early buds for this first harvest of Rose beauty in the open air. But more Roses of the precocious character of the *Maréchal Niel* and a little hardier, if practicable, are much needed for furnishing a good supply of Roses from warm walls through May and the first few weeks in June. But for rosarians that have but room for one Rose on a south wall, there is no Rose to equal the *Maréchal Niel* in quality. True, it is rather tender and almost too precocious, as it needs exceptionally cold weather to keep it dormant after the end of April. But protection not only ensures its safety against cold, but prevents its premature excitement from heat, and thus confers a double benefit.

Planted on walls of all the different aspects, and also in different positions in the open, as dwarfs and standards, this King of all golden Roses may be had in bloom from the open nine months out of the twelve. But all this is by the way, as my chief

object in writing just now was to sound the welcome notes of a good time coming among the Roses. They are exceptionally late, and so are the grubs, and with anything like May weather after this date (the 10th of May), a brilliant season is in store for us. Dormant buds look healthy, and cut-backs are breaking with more than normal vigour, as if pregnant with exceptional fragrance and beauty.

D. T. F.

MERITS OF THE GLOIRE DE DIJON ROSE.

"HANTS" does well to call fresh attention (p. 414) to the many substantial merits of this old favourite. Its popularity can never match its deserts until every cottage, outhouse, or available wall is furnished with one or more of these Roses, and all who can grow Roses in the open have one or more dwarf standards or bushes of this queen among Roses. It is equally at home furnishing the only available yard of ground in the smallest garden of the cottager or the artisan, clothing the proudest mansions of the nobility, or climbing to the top of the highest church steeple. Indeed, some of the finest examples of this Rose ever seen by the writer were those clothing a church porch with a canopy of beauty, and disputing the possession of the roof of a church tower with the rooks. In the latter case the whole of the tower was embowered in Rose shoots and Roses from a single stem.

As a wall Rose or a clother of roofs of outbuildings, &c., this free-growing variety is without an equal. It grows with almost equal luxuriance and blooms with about the same freedom on every aspect, and by planting it freely on all one may almost cut its blooms from the open every day throughout the year.

On the whole, however, I find this Rose most useful on the two extreme aspects of south and north—the former to succeed *Maréchal Niel* on the same aspect, and the latter to continue a plentiful supply of Roses from the open throughout mild autumns and winters up to Christmas.

Two years ago we planted the north wall of a shed considerably overhanging by the roof. The overhanging roof is rather a disadvantage in summer, and involves the necessity for frequent heavy syringings to keep the foliage clean and the plants healthy. But as autumn cools down into winter, and cold rain, sleet, and snow fall, the protection of the roof is invaluable, and ensures many a late cutting of Roses and buds that could not be obtained under less favourably protected conditions. As the season wanes, the quality of the buds and flowers also fine down and improve. The flowers in losing size seem naturally to improve in form, and, what is more singular, deepen in colour; hence the popularity and decorative value of *Gloire de Dijon* Roses for a north wall in the late autumn and winter months. There are some who doubt or deny this improvement in quality in the late autumn and early winter. I would invite any such to try for themselves the culture of this Rose on a north wall. Neither is the *Gloire de Dijon* the only Rose thus largely benefited. *Souvenir de la Malmaison* is coarse almost to uselessness in sunny aspects under bright sunshine, and becomes almost delicate and elegant in the cool autumn tide.

D. T. F.

Some new French Roses.—In a box of nice blooms, received from Mr. J. L. Boyson, of Caen (Calvados, France), of some of the new French Roses now being distributed in this country for the first time, *Lévet's Hybrid Perpetual Madame Bois* confirms the favourable impression made by the fine blooms of it recently seen at Cheshunt. Of *Victor Verdier* family, this Rose appears to possess the good qualities of size, form, and fulness, in addition to being of an attractive and telling rose colour, of a shade between *Marquise de Castellane* and *Marie Finger*. Of *Lévet's* two *Hybrid Perpetuals*, *Madame Léon Halkin* and *A. Drawick*, the former is a good-looking, globular, very fragrant crimson Rose, of which Mr. Boyson thinks very highly, and the latter seems a promising addition to the very dark velvety-crimson Roses, being a well-formed flower, high in the centre, and quite

full; but wherein either variety differs from older sorts of similar colour it is not at present easy to say, for of all colours these crimsons are the most difficult to see in true character under glass. *Mdlle. de la Seiglière* (*Maindron*) is a globular Rose, of a delicate shade of light porcelain pink, the back of the petals paler still, and, though a seedling from *La Reine*, is certainly refined in colour. *Bernaix's Vicomtesse de Wautier* is a rosy Tea, in colour recalling *Madame Cousin* somewhat, and having a pointed bud with petals well twisted together over the centre; but the Tea-scented variety to which Mr. Boyson draws especial attention is *Princesse de Radziwill* (*Nabonand*), a fine deep flower, of a coppery red colour as in *Madame Lambert*, but with the petals recurved at the margin. If the blooms out of doors come as fine as that sent from Caen by Mr. Boyson, this variety will probably prove a valuable addition.—T. W. G.

THE HARDINESS OF TEA ROSES.

MR. T. W. GIRDLESTONE should give note of his locality. He is, indeed, fortunately placed if his Teas have not been subjected to more than 7° of frost this winter. There are few or no Teas that will not bear so much cold with impunity, but should the 7° be doubled, trebled, or multiplied by four, as it was on many occasions this winter, then there are comparatively few Teas that will bear it with impunity without less or more protection. Hence, I consider the 7° test between protected and unprotected Roses as practically useless. The majority of Roses may be trusted to endure 15° Fahr. with but little injury, but as the frost increases from 15° towards zero, then the Teas and other tender Roses begin to suffer severely or be wrecked by the cold. Were I sure that the frost would not exceed 10°, I should dispense with the protection of all Roses in the open. But as this is quite a utopian dream in East Anglia, where frosts of 15° or more are not unknown in May even, we must continue to protect tender Roses during cold weather if we would enjoy their beauty and fragrance to the full in the time of Roses.

As to the best materials for protection, I agree with T. W. Girdlestone that there is nothing like soil, provided the size of the Roses and their distance apart render earthing up practicable. This is not, however, by any means always the case. Occasionally, too, the roots are so numerous and so near to the surface, that it is impossible to earth the Roses up without rupturing many of them, and exposing many more in the bottom of the furrows. The fresh earth keeps the root-stock and base of the shoots cosy and warm enough, but the lacerated roots near the bottom of the furrows have a cold and cruel time of it. It matters little to the plants how severely the ridges may be frozen. So long as the earthen portions of the Roses freeze and thaw slowly in the dark, little or no harm is done. Thus Potatoes, if only covered with an inch or so of soil, may be frozen hard as stones and thaw again with impunity, provided always that both processes are completed without exposure to light or air. However, where Roses cannot very readily be earthed up with soil, *Cocao fibre* refuse, being light, porous, and almost a perfect non-conductor, is one of the very best protectors. Unlike *Bracken*, it need not be cleared away, as it forms a capital mulch for the summer as well as a protector; its lightness and cleanliness commend it highly for either or both purposes. In positions where there might be difficulties in wheeling it on, it could be carried to the Roses in bags or baskets; and ladies who have once had their Rose quarters made clean on the surface, and readily accessible in all weathers by a heavy mulch of *Cocao fibre* refuse, are likely to call for a fresh dressing annually. The Rose roots also seem to like the fibre; and although the manurial value is probably very slight, it conserves the strength of any other manures given, as well as efficiently husband the moisture of the soil.

Bracken fronds are also a most efficient protection, and if for dwarf Teas, these are supplemented by a few *Spruce* or *Yew* branches to hold the *Bracken* in position. The latter also form an addi-

tional protection of very considerable power in themselves. So much is this the case, that in districts where Braeken fronds are scarce, and these branches or others are plentiful, the boughs alone form a very efficient protection to Tea and other semi-tender Roses. Spruce boughs especially possess the unique merit of disappearing piecemeal through the dropping of their leaves or needles, and thus help to solve the most difficult problem of covering, viz., its removal without risk of injury to the Roses or other plants rendered abnormally tender through our artificial coverings.

D. T. F.

Pruning Marechal Niel Rose.—Referring to the inquiry of "V. M." in THE GARDEN (p. 414) I certainly should not hesitate to cut out the old wood to make room for the new, even to the extent of removing all the old if the young wood is likely to fill up the space, since the new growth will produce much finer flowers than that which is spurred back. It is not necessary to cut away all the old at one time; some of the branches may be removed now and some later on as the young shoots require the room. I never had this Rose renew itself from the base but once, and, strange to say, the second growth was, and is now, stronger than the first.—J. C. C.

FLOWERS IN THE HOUSE.

Under this head we propose, during the present season of flowers, to notice things, from whatever department, that are pretty and useful for the house. Any reader who will help us by sending fitting things, or a word about them, will oblige. The simplest things from the smallest garden, and even from the woods and fields, need not be excluded.

I SEND you a gathering of the Garland Flower (*Daphne Cneorum*). It is just now blossoming in profusion. I have some of it in a vase on my writing table in my room, and it scents the whole place. As you no doubt know, it is a little shrub which spreads to a considerable size. The one from which this was picked was, a short time ago, some 4 feet in diameter. Through rough usage about half of it has been destroyed. The remaining half is a mass of bloom.—D. J. YEO.

LILACS FROM M. BALLET.—We have often spoken of the way the French grow their Lilacs and force them, and how much more they make of this beautiful hardy plant than we do. The finest flowers that we have ever seen have just been sent us by M. Charles Ballet, of Troyes. There is Lemoine's double one, prettier than we expected, Lilae de Concel, and, best of all, Aline Mocqueris, one spike of which was 11 in. long. We are surprised at their beauty after four days of travelling!

THE PAU ANEMONE keeps well in water. Mr. Rawson finds it keeps admirably in London.

ANEMONE ROBINSONIANA cut in bud and placed in water to open will come of finer colour; a beautiful rosy glow stripes the blue.—M.

CACTUS DAHLIAS.—During the last few years these have become very popular, and certainly a gardener who has to supply cut flowers in quantity ought to grow them. To get them in bloom early they ought to be strong plants by the middle of May, or the season will be too far advanced before any blooms are fit for cutting, and no matter how early they begin to flower they will produce abundance of bloom till frost comes. They require a deep and rich soil. Our plan is to start the old roots in boxes of light soil in a light, cool house, so as to get them with sturdy growth, almost ready to show flower by the beginning of May, when they are set out of doors in the shelter of a wall, and a slight covering given until the middle of the month, when they are planted out. We take out large holes and put in half a barrowful of

rotten manure and fresh soil, then plant carefully, and put good stout stakes at once, as when grown strongly they become very heavy and are liable to get broken by wind unless very securely fastened. Constance is the best of the white varieties, and Juarezi of the scarlet varieties, the latter being a very strong grower. It is surprising how many blooms may be cut from one plant in a season if the blooms are removed as soon as they are fit for cutting.—J. G. H.

MARGUERITES AS CUT FLOWERS.—I question if there is any cultivated plant that can excel the Marguerite for quantity of bloom that a single plant will produce in one season, as they keep on growing and flowering as if no rest or cessation were needed. About twelve months since I planted out half a dozen of the large-flowered white Marguerite in a border of fairly good soil, and although they were only 6 inches high in May, they were at least a yard in diameter by October, and as perfect models as any trained show plants, although they had grown entirely in their own way. As they were covered with flowers and buds they were carefully lifted and placed in large pots, giving a good soaking of water and setting them under the partial shade of Peach trees, where by syringing daily they soon recovered from the check and began to flower freely, and by the time the leaves were all cleared from the Peach trees they would bear full exposure to sunlight. During the winter they were kept in a greenhouse and were never without some expanded blooms fit for cutting, and during the past two months they have been completely covered with flowers. As these Daisies are in such constant request for all kinds of cut-flower decoration, I feel sure that gardeners who have not yet grown them will do well to include them in the list of specialities for supplying the cut-flower basket, as in addition to the length of time they remain fresh in water, may be added the fact that, by employing flowers of such light and graceful character, it is well nigh impossible to make any arrangement they are employed in other than light and pleasing.—J. G., *Hunts*.

A FRAGRANT WHITE PINK.—Mr. Geo. Bolas, of Hopton, writes:—

What do you think of Clove-scented Pink Mrs. Sinkins grown in a light wooden frame from cuttings put in 4½-inch pots during November, plunged to the rims in pans, with the frame first partly filled with leaves and banked up with ashes? The latter were taken away in the middle of January and a good lining of stable manure was added. The result was in March eight to ten flower-spikes from each pot soon up to the glass. They have been giving a feast of lovely flowers during the last three weeks. These little items give a great charm to gardens of no great pretention. Other Carnations so treated are behaving in the same way, but are not in flower yet.

TOM THUMB VARIETIES OF NASTURTIUM.—Cuttings put in late in autumn in 4½-inch pots and kept from frost produce a blaze of colour in early spring in warm houses, and make a show at once for planting outside in the end of May.

DOUBLE CUCKOO FLOWER.—A beautiful plant, not so much grown as it deserves, varying in colour from nearly white to pale purple; the individual flowers like little lilac Roses, well worth close attention. A glass of it, with some double purple Crown Anemones, is very pretty; it has an interesting old-world look, reminding one of the flower-embroideries of our great-grandmothers.—J.

LATE TULIPS.—How seldom one sees in gardens some of the Tulips that are the very best for cutting. All who want the best for this purpose should be provided with Tulipa retroflexa, of beautiful form and of a clear, luminous-

yellow colour. Another most desirable kind is the one that comes from the Dutch nurseries, under the name of Silver Crown. Both these kinds have the pointed reflexed petals that give a singular grace to the shape of the flower, and a refinement of aspect that is wanting in the bolder, round forms of the greater number of the late Tulips, beautiful though most of them are.—J.

BROAD-LEAVED SAXIFRAGE.—A bold arrangement of this fine plant has a good effect in large rooms, especially if placed in large bowls of silver or white earthenware, or any large receptacle of quiet, simple form and colouring. Where it is grown in large quantities it is best to cut whole crowns with flower and leaves together. The heart-leaved kind is the most suitable, the leaves being handsomely waved at the edges.—J.

TIARELLA CORDIFOLIA.—This remarkably beautiful plant, with its foam-like flowers and beautifully formed leaves of a tender green, daintily flecked with tiny dark red spots, should be grown largely for cutting. Perfectly hardy and free growing, a strong tuft or two will soon make a good stock. It is best to cut out a whole crown or two here and there, as the leaves then group to best advantage with the flowers. If mixed charmingly in a shallow bowl with the large Forget-me-not (*Myosotis dissitiflora* improved), both enduring long, and appearing to grow and improve in the cut state.—J.

ROSEMARY.—Never so late as this year in coming into flower, but none the less welcome; its pale flowers, in perfect colour, harmonise with its dusky grey-green leaves. Good with many cut flowers, and of a rigid build that helps to support any of weak stem or drooping habit.—J.

POET'S NARCISSUS.—The finest single form of this sweet and lovely Daffodil, and the earliest, is *N. poetiens ornatus*. With branches of Sweet Brier it makes a delightful bouquet of sweet scent and fresh, spring-like colouring.—J.

EPIMEDIUMS.—Plants so distinct in flower and leaf should not be forgotten. The best of all is the handsome *E. macranthum*; the flowers in brilliant spikes of canary colour, and the leaves, some green and some bronze, on stiff, wire-like stems, of forms of remarkable beauty.—J.

MARSH MARIGOLDS.—The finest thing we have seen during the week in the house was a large vase of these flowers, gathered in a wood, placed on a little landing of a dark oak stairway. By day or night they seemed to have a new splendour.

MAGNOLIA LENNÉ.—This is very useful on a lawn. The blooms are as large as a goose's egg, and are of a rosy purple colour, and produced in great profusion. It also lasts well when cut. Flowers just to hand from Mr. Crook, Farnborough Grange.

DOUBLE POLYANTHUS QUEEN VICTORIA.—I herewith send for your inspection blooms of my double Polyanthus Queen Victoria, for which I received a first-class certificate at the Auricula and Polyanthus Royal Manchester Show in 1886. The plant is a seedling which came up in my own grounds. Not more than a mile from here was raised the noted Polyanthus Cheshire Favourite nearly eighty years ago. I have seen several doubles from Ireland, but nothing like the one sent.—WM. OWEN.

. A very bright and pretty thing.—ED.

TULIPA RETROFLEXA.—The beauty of the Wood Tulip, or more so. It may be a near relative. Mr. Hartland sends the Persian Tulip—a pretty little kind.

*

AOTUS GRACILIS.—Very pretty when cut with its long, elegant, and dense spikes, which are often over a foot long, covered with yellow and crimson flowers. Sent by Mr. Crook.

*

STREPTOSOLEN JAMESONI.—We figured this in THE GARDEN. It would be difficult to give an idea of its fine orange flame-coloured flowers. It is a very fine summer-flowering plant for the greenhouse, and will, do doubt, become popular on account of its free growth and free-flowering habit. We have not seen better specimens than those just received from Mr. Crook.

*

AMERICAN WOOD LILY (Trillium).—A beautiful thing—not plentiful enough yet for cutting, perhaps. We have not yet tried if it will keep long in a room.

*

ORANGE GLOBE FLOWER (Trollius napellifolius).—Fine plant for cutting, and in effect as good as our Marsh Marigold. As a plant for cut flowers, easy to grow in any moist soil, or in a ditch side, if there be no room to spare in the garden.

*

MISSOURI CURRANT.—Why do not people more often grow this pretty *Ribes aurea*, which is so fragrant and attractive, especially when cut at this time of year!—T. W. GIRDLESTONE.

*

THE OLD DOUBLE WALLFLOWER.—We are glad to see this from Mr. Hartland, of Cork. Rich dark in colour, not a bit like the German monstrosities we see so many of. It is a fine old plant, and we hope he has some thousands of it.

*

NARCISSUS INCOMPARABILIS SEMI-PARTITUS.—In the report of the Narcissus committee in the last number of THE GARDEN a double form of *incomparabilis semi-partitus*, presented as an occasional sport by Mr. Ware, is mentioned. I take the liberty to inform you that I have cultivated for some time a double semi-partitus, which has remained constant for several years, and which, I suppose, I can now consider well fixed. I send you a flower per parcels post; if it is not the same as Mr. Ware's form, it may be a similar one.—J. H. KRELAGE.

* * A fine open form, very pretty in colour.—ED.

*

We are herewith enclosing for your table a truss of *Rhododendron Aucklandi*. It is grown outside, and we think you will find it very beautiful. We originally received the plant from the late Mr. Mangles, of Valewood, Haslemere. We have sent no foliage, as we wished to avoid losing any wood-growth. As the young shoots start they are of a beautiful delicate rose-pink, and add a second season of beauty to the plant.—CHAS. SMITH & SON.

* * A very beautiful delicate colour.—ED.

Propagating Dracænas.—In addition to the various ways of propagating these plants mentioned by "T. B." in THE GARDEN, page 396, I find that if the tops of plants that have lost their bottom leaves, and become unsightly, are cut off and placed in bottles of water, they form roots very quickly. When rooted they can be potted in the usual way; the roots formed in the water take very freely to the soil after potting. When the bottles can be placed in bottom-heat the cuttings root quicker, but they

will do so on the stages or shelves of the stove. Large heads can be rooted in this way in a few weeks without the loss of a leaf.—R. G. G.

PROPAGATING.

SEEDLING FERNS.—After Fern spores have been sown, and the young plants commence to cover the surface of the soil with a Moss-like growth, they require to be carefully watched, as a kind of decay, induced no doubt by overcrowding, sometimes sets in, and will carry off numbers in a short time. Some kinds more readily fall a prey than others, but in all cases by far the better way is to prick them off as soon as the least signs of this decay appear, and in doing so keep away from the new pot any piece that may be the least affected. The soil in which to sow the spores, and also that for pricking them off in, is much better if it can be baked before use, as such treatment will destroy all vegetable and animal life, and a little creeping Moss often does great damage by growing faster and gradually choking the young Ferns. In pricking off as well as in their first potting, most Ferns will grow better if the soil be put in very lightly, instead of being pressed down firmly. An allied class of plants to the Ferns, viz.:

SELAGINELLAS, are, generally speaking, of easy propagation, but still there are a few that do not increase very readily. These are the dwarf cuspidate kinds, of which *S. involvens* may be taken as an example. This sort rather suggests some dwarf-growing Conifer, and it may be increased in the same way as they are, that is to say, by taking cuttings of the shoots, and dibbling them into pots of sandy peat. Of course, the majority of the Selaginellas can be increased by division, but in all cases it is as well to bear in mind that a humid atmosphere greatly assists the formation of roots, and whether divided or simply put in as cuttings, they are in both cases greatly benefited if kept rather close till root action recommences.

PELARGONIUMS of the show, French, and fancy classes that are needed to flower early next spring should be put in without delay, as when struck as soon as this they may be grown on steadily, and in this way a sturdy habit is ensured. The best cuttings are formed of the short-jointed shoots, of which a few are frequently produced towards the outside of the plant, and if cut off carefully they are not missed, and consequently the plant is in no way disfigured. Of course, where it is desired to get as many plants as possible from one particular specimen, it may be cut down after flowering and made into as many cuttings as it conveniently can be, but the above remarks apply only where there is a quantity of flowering plants whose blooms are so much valued that they cannot be cut down yet. These short, spur-like shoots should have one or two of the bottom leaves removed, and then be dibbled into pots, about four cuttings around a 4-inch pot being a very suitable number. The pots should have a few broken crocks in the bottom, and the soil best suited is a sandy loam with a slight admixture of leaf-mould. After the cuttings are put in and watered, they should be placed on a light, sunny shelf, and though they may flag a good deal and lose the greater part of their leaves, they will strike just as well as if shaded, and are much less liable to grow up weakly. A good deal of the after success depends upon the selection of the cuttings, and guarding against their becoming drawn during any of the stages of their growth.

THE ROSEY JASMINE (Mascarenhasia Chrnovi-ana), of which a coloured plate was given in THE GARDEN a few years since, is by no means an easy subject to propagate, for if cuttings are formed of the young shoots they are very apt to decay, while if allowed to get too old they will stand for months without rooting, and perhaps die at last. I have had the greatest measure of success by taking as cuttings the shoots when they are about half ripened—that is to say, just as they commence to get woody in texture. The cuttings are then dibbled around the side of a pot 3 inches or 4 inches in diameter, the soil used being about equal proportions of loam, peat, and silver sand. The pots must

be well drained, and when the cuttings are inserted, placed in a close propagating case in the stove. After about a month they should be plunged in a gentle bottom heat, to encourage the formation of roots. Where there is no propagating case at hand, the cuttings may be covered with a bell-glass; and a very useful method when other appliances are wanting is, in the case of cuttings requiring to be kept close, to take the pot in which they are and drop it into a larger one, filling up the space between the two pots with sand or soil. The larger pot must be deep enough to allow of a pane of glass being placed over the top without crushing the cuttings; and of course these close pots will need attending to in the matter of watering, shading, &c., just the same as a propagating case—which, indeed, they really are.

TILLANDSIAS, VRIESIAS, and most other Bromeliaceous plants can be increased to a certain extent by means of division, or by detaching suckers, but of some, seeds are occasionally obtained, and when such is the case they can be raised in an almost unlimited quantity, for the seeds of many kinds are very minute and germinate well. I have raised a large quantity of the beautiful *Echmea fulgens*, of which almost every seed must have grown. The seed was sown as soon as ripe in pans of sandy peat, the top portion being passed through a fine sieve, while the bottom soil was rather rougher and more fibrous. The surface being well watered the seed was at once sown thinly thereon, and owing to the wetness of the soil it directly adhered thereto. A slight covering of dry sand being sprinkled over the seeds, a pane of glass was laid on each pot, and allowed to remain on till the young plants made their appearance. As soon as they could be conveniently handled they were pricked off in much the same kind of soil as before, and some placed in a close case made far more rapid progress than those that were kept in the ordinary atmosphere of the stove.

ALOYSIA CITRIODORA (the Lemon-scented Verbena), common though it be, is a plant that many fail to strike in a satisfactory manner, yet if a certain method be followed it will root readily. The plant intended for propagating from should be placed in a little heat, and will then soon push out quantities of young shoots. These shoots must be taken in their soft and succulent condition, and, being without delay dibbled into pots of light soil, should be kept close till rooted, which will only occupy about a fortnight. If they are then gradually hardened off and potted into rather light rich soil they grow away at once without any check.

CEANOTHUS.—We employ some of the *Ceanothus* for flowering under glass at this season, and find that the shoots which are then produced afford a ready means of propagation, for they strike root without difficulty. The time to take them is just as the succulent stage is passed, and they should be kept close till rooted. At the same time they are rather liable to decay if kept too close or too heavily shaded, so that errors in this respect must be especially guarded against. They should be potted off as soon as struck, for nearly the whole of the growing season is still before them.

PRIMULA SIEBOLDI, which every year at this season attracts a considerable amount of attention, is one of the easiest of all the Primulas to increase, as pieces of the roots grow so readily, even if cut up very small. The best time for the purpose is in early spring before they start, but they will also grow now, though they will not be so strong by winter as if struck earlier.

ALLAMANDAS can all be propagated without difficulty from cuttings with the usual treatment of many stove flowering plants, except *A. grandiflora*, which curiously enough succeeds best when grafted on one of the other kinds, such as *A. Hendersoni* or *nerifolia*. Sidegrafting is the method usually followed, the scion consisting of a moderately firm shoot of the current season's growth, or even a single joint will be sufficient. In any case care must be taken that the union is as perfect as possible, and if tied securely in position and kept close no grafting wax or other covering will be required. T.

STOVE AND GREENHOUSE.

T. BAINES.

CEPHALOTUS FOLLICULARIS.

(THE NEW HOLLAND PITCHER PLANT.)

THIS is one of the most curious and interesting little plants in cultivation. It is the smallest of all the Pitcher plants. Botanically, and also in its appearance, it is widely different from any of the *Nepenthes*, which latter genus is usually looked upon as the representative Pitcher plants. It also differs from any other of the insectivorous plants. In *Nepenthes* the pitchers are mostly produced at the extremities of the leaves, being an extension of the mid-rib; in the *Sarracenia*s the pitchers are simply the leaves, which, for more or less of their length, are hollow and distended; but in *Cephalotus* the pitchers are independent of the leaves, and are supported on stalks that spring from the stem of the plant. The pitchers are beautifully formed, with a lid similar to that of *Nepenthes*, but hooded; the mouths of the pitchers are armed with a row of strong hooked spines, that prevent the egress of the insects that are allured within them by the fluid secretion which they contain. When the plants are strong and grown under the influence of sufficient light, the pitchers assume a blackish brown colour, almost as dark as ebony. They are large in comparison to the size of the plant and leaves, in a strong example attain a length of about 2 inches.

The plant, when in good condition, produces crowns or suckers freely from the main stem, and its increase is effected by separating these. They are best when taken off in spring, severing them close to the stem. At the time named the suckers will generally be found to have produced roots. Care must be taken to secure these without their being injured. The best material to grow *Cephalotus* in is one half good fibrous peat and one half Sphagnum, both chopped into small bits, adding some crushed charcoal and sand. Very small pots will be required at first. These must be well drained, and the potting compost pressed firmly about the base of the stem, giving water when the operation is completed, so as to moisten the material fairly. The little pots should then be plunged in others two or three sizes larger, filled with Sphagnum, putting a small bell-glass over each plant. Place in an intermediate or moderate stove temperature close up to the glass, and shade when the weather is sunny. Here they will soon get established and will form roots freely; now give a little air by tilting the glasses on one side. It will be best to keep the plants in an intermediate temperature during the ensuing winter. As early in spring as growth commences move them to pots a size or two larger, plunging, as before, in others that are bigger. The Sphagnum used for plunging must from the first be kept constantly moist. By attending to this the moisture will be absorbed by the pots containing the plants, so that the soil will be in less danger of getting dry, a condition that must not be allowed either during summer or winter, as this *Cephalotus* partakes much of the nature of our British Sundews in needing to be always more or less moist at the roots, and kept wetter during the season of active growth than when dormant. As it is desirable to get the plants on so that they may attain size and strength with as little delay as possible, it will be well to keep them during the second summer in intermediate warmth, tilting the glasses higher so as to give more air. As the season advances the bell-glasses may be dispensed with altogether, but in this case the plants should be stood close against the glass at the end of the

house away from where air is admitted, so that they may have the benefit of a still atmosphere. So situated the plant always did the best with me, though I have seen it in good form when stood close to the front lights where air was given; but I cannot speak as to whether the plant in question was continuously subject to such conditions or was temporarily stood where it received a direct current of air. But to give the pitchers the deep rich colour that is so essential to their appearance, the plants must have a place as near the glass as they can be got. The influence of light that comes through the upright glass at the end of a house in colouring this and some other plants—such, for instance, as *Sarracenia*s—I have found to be more effectual than that which is communicated overhead through the roof.

It often happens that this and other highly interesting plants that do not succeed anywhere or anyhow, are found to do better in some particular position in the house where they are grown. The observant cultivator will endeavour to find out such positions and not fail to note the effects. If there is one thing more than

turn yellow and fall off, after which the plants are of little value.

PIMELEA SPECTABILIS.

THIS plant, of which we here give an illustration, may now be seen flowering profusely in Mr. Williams' nursery at Upper Holloway. It was introduced to this country from the Swan River district of Australia nearly fifty years ago, and has always been a favourite with growers of New Holland plants. The genus belongs to the Daphnoid family (*Thymelacacee*), and contains numerous handsome species, which are alike useful in the conservatory or for exhibition purposes, as they travel well without bruising. This plant is a strong, yet compact grower, a profuse bloomer, and of tolerably easy culture. The soil best suited to this plant is a mixture of peat and loam, in the proportions of about three parts of the former to one of the latter; to this should be added sufficient sharp sand to make the whole feel gritty, whilst thorough drainage is indispensable. After flowering is over the plants should be cut back tolerably hard, in order that they may be well furnished with foliage at the bottom. Potting

Pimelea spectabilis. Engraved for THE GARDEN from a photograph.

another which cultivators have given insufficient attention to, it is the widely different influences that light has on plants when it reaches them through the glass at different angles.

As the plants increase in size they necessarily require more root room, yet a 4-inch pot is large enough for a full grown specimen consisting of several crowns; when this size is attained each plant will produce pitchers that will form a closely packed circle all round outside the leaves. The plants should be syringed overhead daily through the growing season, and, as already stated, must never have their roots dry. After the first or second season when the suckers are taken off and established, the temperature of a warm greenhouse will be more conducive to the plants continuing in a healthy, thriving state than if more heat is used, for though the progress is quicker yet the growth is softer. It is necessary to keep a continual look-out for aphides, which often attack the plant, getting on the undersides of the leaves, where they are sometimes not noticed until much harm has been done. If the parasites remain undisturbed for only a short time they cause the leaves to

should be performed just after the stems begin to put forth young shoots; the soil should be made very firm, and water must be carefully supplied until the roots begin to get established in the new material. Just at this time a slightly warmer and moister atmosphere will be beneficial, but when somewhat established the plants may be removed into the greenhouse again. During the earlier growth the shoots should be pinched off once or twice to keep the plants bushy, but this stopping of the growth should be discontinued after the month of July, or they will not have sufficient time to ripen up and form flower-buds for the ensuing spring. *P. spectabilis* is characterised by its linear-oblong, somewhat glaucous, smooth leaves. The flowers are produced in large woolly white heads upon the points of all the shoots, and they last in full perfection for a considerable time. The variety *rosea* is rather a stronger grower than the typical plant, and the flowers are all tipped with rosy pink, thus rendering it very distinct and a fit companion for the species. G.

Erica Cavendishi.—The beautiful yellow flowers of this Heath cause it to stand out con-

spectuous from all other members of the genus, and as yellow blossoms are (except those of the *Cytisus* and *Coronilla*) by no means very prominent in the greenhouse at the present time, it is on this account very attractive. This *Heath* is of a good, sturdy, free-growing habit, and its constitution is such that it will succeed under the usual treatment accorded to the general run of hard-wooded plants. The compact, bushy growth and handsome dark green foliage of this *Heath* render it a very ornamental Evergreen, irrespective of flowers. The neat little bushes of it now brought into Covent Garden Market are good illustrations of successful plant culture.—H. P.

DISA GRANDIFLORA, VARIETIES AND TREATMENT.

MY friend "Delta," recounting his success with *Disa grandiflora*, makes one or two remarks in THE GARDEN (p. 411), which in the interest of cultivators of this fine plant call for notice. I rather suspect I am the friend who recommended him to break it up, a practice which he does not approve. But he either mistakes what was meant, or he argues on too slight an induction. It was not meant that they should be needlessly divided, but only when the pots had become quite full of roots and growths, which with me always happens the second season at farthest. After that, if left undisturbed, I invariably found that they suffer. I once grew a plant without dividing until it occupied a 14-inch pin, but the growths made for the edge, and the older parts of the plant in the centre died off. This was Nature's way of effecting a breaking up. I would advise "Delta" to think twice before deciding that separation is wrong, because the pot-fal which he did not separate last autumn is stronger now than those which he did. My experience is that it is a plant that likes plenty of root room, and that pots are very preferable to pans, as affording greater abundance of drainage, in which the roots love to ramble, and, at the same time, ample potting material. The best result as regards strength of spike is obtained by one strong plant in an 8-inch pot.

In all this "Delta" and I are probably at one when we understand each other as to what breaking up means, and the degree in which it is to be practised. But I fear my friend and I are more really at variance in his estimate of the relative values of *D. grandiflora* *superba* and what is sometimes spoken of as the *Glasnevin* variety. This latter he says is "very inferior in the quality of its flowers," and he doubts "very much whether he shall care to increase his stock of it." That the *superba* variety is a shade or so deeper in colour I at once admit, but nothing could be farther from the fact than for anyone to suppose that the so-called *Glasnevin* variety is hardly worth culture. The idea would be ludicrous to anyone looking at a bunch of the two varieties in full flower. Old florists like my friend and myself, who have had our eyes sharpened by *Auriculas*, can at once distinguish the difference; but I know that I have found some difficulty in convincing outsiders of its existence. Surely, then, when the difference in colour is but slight, and the *Glasnevin* variety is found by many to be robuster and of easier culture, it can never fail to be justly considered one of the most beautiful and valuable plants in existence. I may add, in order to guard against misconception, that I grow both varieties, and find them to do equally well under similar treatment.

Clophran, Dublin.

FREDERICK TYMONS.

Soil for Azaleas.—Like most other gardeners, I have held to the firmly fixed idea that peat was the correct thing for *Azaleas*, and there can be no doubt but that they are grown to the greatest perfection in peat alone; but there is such a vast difference in the quality of peat in different parts of the country, that I feel sure, unless one is a good judge of soils, that the plants in many cases are literally starved. Several instances have lately come under my notice of exceptionally healthy and free-flowering collections of *Azaleas* that have been grown in soils quite different to the orthodox mixture. In one case I was struck not only by the quantity, but also by the quality of the bloom on some old

Azaleas, and asking the person in charge what kind of soil they were potted in, he said about half peat and half good stiff loam, and certainly the difference in the appearance of the plants since they had been repotted was extraordinary. They were not grown in one of the places where a regular *Azalea* grower was employed, but where a jobbing gardener came once a week, frequently to find some of the plants require soaking from being so excessively dried up. Possibly some large growers of these gorgeous flowers can give a little information on the soils which they find produce the best results, for I must own that my faith in peat alone has been rudely shaken of late, and many others besides myself would like to know whether they can substitute something more lasting and satisfactory.—J. G. *Hants.*

MANURE WATER FOR CAMELLIAS OUT OF FLOWER.

WHETHER we count the mere numbers or estimate the gross mass or bulk of *Camellia* blossoms, we must be almost equally impressed with the enormous strain they exert on the plants. Blooming, as they often do, in succession for four or five months at a stretch, the plants must be almost exhausted of productive force by the time the last blooms fade. Hence the importance of supplying stimulants to the roots, as their heads make a fresh start into wood-making.

This is also the only proper time to prune *Camellias*. By contracting the area of their tops through the removal of weakly and the cutting back of straggling shoots, the growing force is concentrated and virtually strengthened. With the advent of fresh growth above, the roots also make a new start underground. They are thus prepared to make the best use of all food presented to them, whether in a liquid or solid state. Hence this is the best season for furnishing *Camellias* with larger pots or new borders. But whatever compost may be provided for *Camellias*, its feeding properties are speedily exhausted. Neither is it prudent to give the roots very rich soil, for the richer the soil the sooner will it be virtually consumed and its mechanical texture broken down. The latter is by far the most important factor in such long-enduring plants as *Camellias*. Given a good mechanical medium and sufficient drainage to preserve the roots in robust health, it is the simplest thing in the world to supply them with food when needful.

All this is of the more moment, as *Camellias* are by no means gross feeders, except during one short period of the year. From the time the flower buds are set and fairly formed until they are fully unfolded the plants feed very sparingly. Stimulating food during this long period proves mischievous, and is one of the most fruitful causes of bud-dropping. Grown in rich composts, *Camellias* perforce are often too highly fed during eight or nine months out of the twelve, and this plethora of food when it is not needed is one of the most prolific sources of jaundice and other diseases. But during the period of active growth it is well-nigh impossible to over-feed *Camellias*. The plants do so much in such a limited time, that they need to be fortified by abundant supplies of food. *Camellias* during the short period of growing not only recoup themselves from the effects of previous exhaustion, but add greatly to their size and form, and considerably develop their bloom-buds for the following season. They also form new roots as well as extend their top-growth, and the vigour and health of both mostly depend on the abundance, richness, and suitability of the food provided. Another element of great importance has to be taken into account. It is of almost vital importance that the food should be readily absorbed and promptly assimilated, and converted into such products as shoots, foliage, flower buds, for the time, as we have already seen, is short, and the period during which *Camellia* roots can freely or greedily absorb food is shorter still, the time of maximum consumption of food probably not greatly exceeding a month or six weeks. Hence, should fresh solid manure be given, but little of it will be sufficiently soluble to be absorbed during the season of abnor-

mal root-bunger or activity. Unabsorbed manure in pots is always a source of danger, as it tends to injure or destroy the texture of the best soils. The roots may positively starve in a virtual dunghill while the manure is preparing for use.

For all these reasons liquid manures are best for *Camellias*. If not too strong, these are absorbed at once and converted into branches, leaves, and flower-buds before solid manures are sufficiently broken down to be used at all. Any excess, too, is run off through the water, and little injury is done. As to the sort of liquid, closet water, house sewage, liquid formed from pigeon, sheep, and cow manure, soot, and guano have been found the most suitable. The most striking results in verdure and vigour of growth were obtained by the use of closet water very much diluted with rain water that fell on a contiguous outbuilding. In less than a week the whole character of an entire house of *Camellias* was changed by its judicious use, and before their growth ended there was hardly a trace of a pale leaf in the entire houseful, though the collection was characterised by a semi-jaundiced shade of colour previous to the use of the liquid manure. The next best manure water for *Camellias* is that made from soot in the ratio of a bushel to twenty or thirty gallons of water. The soot should first be converted into paste—no easy matter—then incorporated with the water, left to settle for twenty-four hours or more before use, and drawn off clear.

HORTUS.

AURICULAS.

I HAVE read the remarks by "R. D." in THE GARDEN (p. 413) upon *Auriculas*, old and new. It must be pleasant to "R. D.," as it is to myself, to see the interest in these beautiful spring flowers not only sustained, but increased. The exhibitions in London, Manchester, and Edinburgh were very successful. In the Scottish metropolis the room where the show was held was crowded with visitors. Cannot our Irish friends get up an exhibition in Dublin? It would increase the love for the *Auricula* there, which seems to be declining at the same ratio as it is increasing in England and Scotland. The Rev. F. Tymons does not write hopefully of the present and future of floriculture in Ireland. I do not quite agree with "R. D.'s" estimate of green-edged *Auriculas*. I cannot recommend *Trail's Anna* at all; it has been grown in our collection with the greatest care for ten years, but it, like Mr. Simonite's *Talisman*, has not fulfilled its first promise of good quality; in fact, there are but two green-edged *Auriculas* to be depended upon to place in a collection of six at a good exhibition, viz., *Prince of Greens* and *Rev. F. D. Horner*. *Rev. George Jeans* and *Imperator J* threw out as entirely untrustworthy. The best grey edges are *George Lightbody*, *Alexander Meiklejohn*, *Lancashire Hero*, *John Waterston*, *Frank Simonite*, and *Richard Headley*. In white-edged flowers I do not predict very great things of *Reliance*; the tube is too large, and it is altogether wanting in quality. Conservative increases very freely, but requires good treatment, as the plant is very small when fully developed. *Smiling Beauty*, *Acme*, and *John Simonite* are the best of the white-edged varieties. Mr. Horner's new varieties will not only add brilliancy to a weak class, but they will quite revolutionise it. *Maggie* is the best white yet seen, north or south. The tube is a rich deep yellow. I have heard it described as "glowing gold;" the anthers are bold and heavy; paste pure white, dense, broad, and quite round; ground colour quite black; edge of the densest and purest white yet seen. The flowers last long in beauty.

Amanda may be termed a new departure; the tube is quite yellow, and it is the only violet ground yet introduced with a deep yellow tube. It has a good white edge, which also lasts well, as the plant exhibited in London had been in flower for three weeks.

In self-edged varieties "R. D.'s" selection is the best that could be made under the circumstances, but in six years more I hope to see most of them weeded out from every good collection. I hear that *Heroine* (*Horner*) is likely to be distributed this year, probably through Mr. Simonite. Growers will

not be slow in raising from its seedlings which cannot fail to be great improvements on all the old sorts. "R. D." has omitted one of poor Mellor's best flowers from his list of selfs; it is named Negro, and was very good here this year. It cannot be expensive, as it was sent out two years ago at half a guinea.

Dulcis is one of the best of Mr. Horner's new selfs; it would beat Heroine but for its paste, which is not quite so good, because not so broad, as that of Heroine. It is in this latter point that Heroine excels. In Ellen Lancaster and some of the older sorts the paste is far too narrow.

Rubra is a rich, dark velvety red, and if we add Mrs. Horner as a violet self, we have three new sorts recently exhibited of surpassing excellence.

I would urge upon all new beginners the importance of obtaining the very best varieties to start with—never mind the price. They are really the cheapest in the end. It is easy to raise seedlings from them; but to begin raising seedlings from the sorts named by "R. D." would be to court failure. The young grower would find himself in the year 1877, not 1887, and would have to work at the least for ten years before he could reach the point we have now arrived at. Surely it is better to pay five shillings or so more for a plant and be in the same age as one's contemporaries.

In reference to the alpinas, the same remarks also apply. Some of those named by "R. D." were raised more than twenty years ago, and are now quite out of date. Further, it is much easier to obtain good varieties from seeds. I have raised a thousand seedlings from green-edged Auriculas in an effort to improve a weak class, but as yet have only obtained one good variety. Two years ago I raised from seeds 250 plants of a single alpine cross, and out of that number I have saved forty really good sorts, as good and many of them better than the parents. The alpine varieties are also very hardy, and form excellent colonies and groups in the rock garden. J. DOUGLAS.

Crassula jasminæa.—This is an extremely pretty little greenhouse plant, and one that will remain in flower a considerable time. It forms a dense, close, branching mass about 6 inches or 8 inches high, and each shoot being terminated by a cluster of white blossoms, the whole plant is quite a mass of that tint. It is nearly allied to the well-known Kalosanthes coccinea, and the individual flowers much resemble each other in shape, but the colour is quite different, as well as the entire habit of the plant. It has been, I believe, known in this country for a long time, but it is only within the last half-dozen years that it has been extensively cultivated by one or two market growers, and thus quickly became popular. Like most of its allies, this *Crassula* is a plant of easy culture, for cuttings will strike root without difficulty, provided they are not over-watered, and from their succulent character they need to be kept pretty dry during the winter, and also in a light position.—H. P.

Lantanas in bloom.—The *Lantanas* certainly possess one strong claim to recognition, viz., their long period of flowering, for under favourable conditions they will bloom more or less for three parts of the year, and their blossoms are at all times very attractive. We have some little bushes in 6-inch pots that were wintered in a structure kept at an intermediate temperature, and they are now completely studded with their clusters of bright-coloured flowers. Though so attractive on the plant, the strong smell which pervades the whole of them, especially when bruised, is against their being employed in a cut state, at all events where they will be closely inspected. A noteworthy feature with regard to the blooms of *Lantanas* is the great change of colour which takes place after they have been opened for a day or two; for instance, some will, on opening, be bright yellow, which changes to deep pink. As one cluster will contain flowers in all stages of development, the gradation in colour is thus rendered the more pronounced. *Lantanas* are plants of the easiest possible culture, the treatment accorded to *Fuchsias* suiting them perfectly, and they strike root just as easily. The cuttings must

be formed entirely of the young growing shoots, and if kept close they quickly root. Red spider is very apt to attack them, but an occasional syringing will keep it in check. A few good varieties are *No Plus Ultra*, orange when first opened, changing gradually to magenta-purple; *Favourite*, salmon-red, changing to purplish; *Pluie d'Or*, light yellow; *Distinction*, bright orange-red; *La Noire*, white; and *Magenta King*, purplish magenta.—H. P.

GREENHOUSE RHODODENDRONS.

THESE are very handsome plants for the decoration of the greenhouse and conservatory during the spring months, and they are so easily grown that anyone might manage to cultivate them. The Himalayan group comprises all those with large flowers, such as *R. Dalhousie*, *Countess of Haddington*, *exoniensis*, *Veitchianum*, &c. They are not expensive plants, and their foliage is at all times very beautiful. They will succeed in any part of the greenhouse, either on the sunny or shady side of it, and they do not require to be placed so close to the glass as some plants do, and when they have made their growths, if space is then required in the greenhouse, they may be placed out of doors. I fancy the buds set quite as well out of doors as they do in the greenhouse. Even as foliage plants some of them are very ornamental, *R. Edgeworthii* for instance. Some of the stronger growing species make excellent conservatory plants if they can be planted out in a good deep border of turfy peat, and if this is not over-plentiful a little yellow loam may be mixed with it. For pot culture we drain the pots well, as we expect to give them plenty of water at the roots, and unless they are well drained this does not pass freely away. For the very small, fine hair-like roots of *Rhododendrons* become compacted so closely together that I have known water stand for some time on the surface. A good plan is to mix with the potting soil a little broken charcoal. Light, fibrous peat torn up by the hands is the best material in which to pot them; a very little loam added is useful, and a small quantity of decayed manure or leaf-mould is beneficial. The same treatment applies to the *R. javanicum* group, except that it requires a rather warmer temperature all the year round, and especially in winter. There are many very handsome varieties of this group now in commerce, and some startling additions are being made this year. The varieties with trusses of flowers shaped like a double Balsam—*R. balsaminiflorum* vars. *album* and *aureum*—are now being sent out; also the buff-coloured *R. President*. It is in its way quite distinct and remarkably pretty. I have had ample opportunity of watching the development of these plants, and can testify to their free vigorous growth. Another excellent characteristic is this, that they can be propagated quite easily from cuttings. J. DOUGLAS.

Veronica Hulkeana.—This New Zealand *Speedwell* is very different from most of the species which are natives of that region, but it is none the less beautiful, and, like the other members of the genus, is of very easy culture. When planted in a warm, sunny border, it will survive most winters around London, though it is frequently severely injured, but further south it may, like the rest of its class, be accounted quite hardy. Apart from this mode of treatment, it readily lends itself to pot culture, and with us where it has been wintered in a greenhouse is now in full flower. It is a plant of rather erect habit, and the blooms, which are borne in terminal branching panicles, are of a very pleasing shade of pale lilac. It can be readily grown into neat little flowering specimens in pots 5 inches or 6 inches in diameter, and furnishes a pleasing, and at the same time, uncommon tint among greenhouse plants. It has been known in this country for many years, but is still quite uncommon.—H. P.

Magnolia fuscata.—In answer to your correspondent "D. T. F.'s" question in *THE GARDEN* (p. 442) of your last issue with regard to the temperature best suited to the successful cultivation of the above-named shrub, I may say that all it requires is protection from frost, and that I have always found it thrive admirably and bloom abundantly when grown in the ordinary greenhouse.

Anyone visiting the temperate house at the Royal Gardens, Kew, will find a fine bush of this most delightfully scented shrub planted out therein and perfuming the house for a long distance round with its exceptionally powerful fragrance. As to what your correspondent Mr. Burrell says as to the growth of this shrub, I can only speak from my own experience thereof, which is confined to pot-grown plants and the fine specimen above referred to in the temperate house at Kew, which though it has evidently been there for many years is now only about 5 feet in height, though I should say nearly 2½ feet or 3 feet in diameter, which proves it to be a slow grower. W. E. GIMBLETON.

Hovea Celsi.—This is one of the most lovely of the New Holland plants; that alluded to in *THE GARDEN* (p. 112) must have been a striking object in the greenhouse or conservatory. It has a tendency to become of a rather straggling habit as it increases in age, and tying the shoots down and over each other it forms an object not pleasant to contemplate. The best way is to keep the plants close to the glass, shade as little as possible, and admit plenty of light and air.—J. DOUGLAS.

DARWINIAS.

THIS is a small genus belonging to the family of Fringe Myrtles. All the members here enumerated are extremely beautiful and popular. The species which we here refer to are somewhat Heath-like in general appearance, of free-branching habit, and when grown into specimens, or even moderate-sized plants, are very useful for conservatory decoration. *Darwinias* require care to grow them well, and both care and attention to keep them in health when they have attained to specimen size. In potting, use good fibrous peat, broken up rather roughly, plenty of clean, sharp sand, and a small portion of light loam. The new soil must be pressed very firmly, avoiding injury to the roots. We prefer them to be rather pot-bound than have a great quantity of unused soil about their roots. Let the crown of the plant stand higher than the sides of the soil, so that no water can remain round the neck of the plant. The drainage must be carefully attended to, and water and air administered judiciously. Respecting temperature, we cannot do better than refer our readers to the hints upon the natural surroundings of these plants given under the genus *Gompholobium* in *THE GARDEN*, April 30, p. 394. We have previously remarked that *Darwinias* are free-branching plants; they, nevertheless, when young must be frequently stopped during the growing season in order to become well furnished with lateral shoots. This being accomplished, and the plants having become well balanced, only the tops of the stronger shoots will require stopping, and this should not take place after the middle of June if flowers are required early the next season. Very little shade is necessary for these plants, and they will be all the better for full exposure to the sun and air through the months of July, August, and September if the last month remains fine. This exposure thoroughly ripens the wood and causes the flower-buds to set, whilst the involucres by this treatment become more highly coloured. After this remove them to the greenhouse, which must have a dry atmosphere with a free circulation of air without draught. They are known also in gardens by the names of *Genetyllis* and *Hedaramas*. The following are the most showy kinds:—

D. TULIPIFERA.—This is a robust, Heath-like plant, attaining a height of from 2 feet to 4 feet, erect, and much branched; leaves opposite, sessile, oblong-obtuse, dark green on the upper side, ashy grey beneath; flowers in dense heads, terminal on all the shoots (in well-grown specimens)—these are, however, small and unattractive, but the large ovate, highly coloured involucres which surround them are very attractive and persistent; the ground colour is white and pale straw colour, flaked and streaked with crimson. It comes from Western Australia, and blooms during April, May, and June. It is also known as *Genetyllis macrostegia*.

D. HOOKERIANA. known also by the name of *Genetyllis fuchsoides*, is a more slender plant than

the preceding; otherwise it resembles it in general appearance; stems reddish brown; leaves sessile, linear-oblong, dark green above, pale below; involucre terminal, pendulous, bell-shaped, deep red, and, like those of all the species, very persistent; but it is bad policy to allow them to remain long enough to exhaust the constitution of the plant, as weak growths and very few flowers the following season will result. It blooms during April, May, and June. Western Australia.

D. FIMBRIATA.—This is a charming small-growing species, its soft, rose-coloured involucre forming a beautiful contrast to the other species. It has not, however, found so much favour amongst plant growers hitherto as it really deserves, perhaps on account of the fashion for decided colours, which this species lacks. It is a slender, dwarf-growing plant with terete branches, and small, sessile, obtuse leaves, which are ciliate at the margins and dark green; involucre terminal, pendulous, bell-shaped, about an inch long, beautifully fringed round the mouth, and of a uniform soft rose colour. It blooms during May and June. South-west Australia. W. H. G.

FUMIGATING.

JUDGING from experience, the art of fumigating is one of the simplest possible; but, judging by the elaborate machines or utensils patented and sold for the benefit of those who must fumigate, it seems to be exceedingly complex. It may be possible that some plants need exceptionally well-strained smoke ere it comes into contact with them; but still I am not sure that the danger, if there be really any, lies so much in the nature of the utensil from which the smoke passes as from the nature of the material which is consumed. We almost universally employ Tobacco paper or rags. Now, pure Tobacco at 3s. 6d. per lb., and then of a refuse form, and, as facts have shown, one-half water, is rather a costly material, and far too rapidly consumed; rag I have found dangerous even to such hardy things as Roses, but that may have been accidental. Still, I greatly prefer good paper; but that, too, differs appreciably in quality. I have used some which rendered existence within the smoke intolerable for but a moment, whilst others have proved remarkably mild and innocuous. Without doubt the capacity of human beings to endure existence in a house under fumigation or otherwise offers a pretty fair test of the merits of the material consumed; still, even the best of Tobacco paper is relatively cheap and so easily employed, that there is no excuse whatever for having aphid in a plant house. Very likely my experience of the process of fumigation is an exceedingly limited one; still, there is not much difference in the effect let the conditions be what they may. When intelligently conducted, of course, some things will bear more smoke than others, but those are points well understood by competent gardeners. Of late my chief experience has been confined to a large span-roof house devoted to Roses. The house is imperfectly constructed, and from the ridge the smoke escapes rather freely, hence it is needful that the house should be filled with smoke quickly to ensure a good smother for some fifteen or twenty minutes. My most useful utensil for this purpose is an old galvanised iron foot-bath, holding about a peck; this has a few holes in the bottom. The process is simple enough. A quantity of cotton rags is burnt to form tinder, and as soon as the flame is over, some Tobacco paper is added slowly until enough is laid in for the requirements of the house. Then I lay over the top some damp Moss, this latter serving at once to cool the smoke as it is emitted, and to press the paper down as consumed. Combustion is even and steady, but a big volume of smoke is quickly emitted, and the house soon full of the vapour. Nothing could be simpler, and because the draught is slow, there is no danger of flame bursting out. I prefer this trivial contrivance to the most costly patented apparatus, and when the material burnt is good it is always most efficient. Such a plan can be followed by any amateur, and inflicts upon him only the smallest inconvenience, as there is no reason whatever for

entering the house once the paper is properly ignited until the door is opened to allow the smoke to escape. I received the other day an elaborate utensil patented specially for fumigating. It resembles a travelling tinker's fire-pot. It is of sheet-iron, stands on a tripod, has a false bottom, in which to place red-hot coals; and in the receptacle above, in which the Tobacco paper is placed, a funnel in the centre having holes in it. This is intended to promote draught. There are also what may be called air-shafts fixed on the outside of the barrel, through which air can pass to the inside. The whole is surmounted by a lid, whilst around the top of the barrel are numerous holes out of which the smoke can escape. The thing is doubtless of an ingenious nature, but seems needlessly elaborate. I tested it against my foot-bath, and found that it was less effective in throwing out a body of smoke quickly, the funnel inside interfering with combustion at first, and then later promoting so rapid a draught, that flame burst out twice, and on the second time I removed the thing altogether. Possibly I am incapable of duly appreciating the true merits of this and similar contrivances, but that is my fault. Still, some other persons may be of my opinion. A. D.

Dwarf German Scabious in pots.—These are very useful when grown in pots for winter flowering. Seeds may be sown about the middle of May, and when the plants are large enough they may be grown on and finally potted in 8½-inch pots. If grown out of doors all the summer and then placed in a cold frame, and brought into a warm house when the days become short, dull, and damp, the fire-heat helps them into flower. The variety grown by Mr. Roberts at Gunnersbury Park is dwarf and free-branching, makes nice specimens in pots, and produces very fine and handsomely formed flowers. Some of the dark varieties are remarkably good, and a packet of seed will yield an excellent assortment.—R. D.

Beaufortia splendens.—This is among the best of the Bottle-brush plants, as these Australian shrubs are commonly called, and so beautiful is it, in common with several others of the same class, as to make one long for a return of these plants to popular favour. All the different hard-wooded greenhouse plants, beautiful though they be, are now under a cloud, but the time will no doubt come when they will be generally grown. The neat habit of this *Beaufortia*, and the fact that it will flower freely in a small state, are great points in its favour; but still it is by no means the only desirable member of this class, as mention may be made of *Metrosideros*, *Melaleuca*, and *Callistemon*, one of the best of this last being *C. rigidum*, a large-growing kind that requires a good-sized conservatory for its full development, and when this can be afforded it the large clusters of glowing crimson-coloured stamens make a goodly show, and not only do they remain in beauty for a considerable time, but a succession is often kept up for months. Seeds of several of this class are at times imported from Australia, and, generally speaking, they retain their vitality well, and germinate without difficulty. A light open soil in which peat predominates is a very suitable compost in which to sow the seeds, and from their minute character they must not be covered too deeply. Cuttings of the half-ripened wood will strike if put in sandy peat and covered with a bell-glass, but they will all remain some time before they root. In common with most other plants, those raised from cuttings flower more freely in a young state than seedlings.—H. P.

SHORT NOTES.—STOVE AND GREENHOUSE.

Woodlice in stove.—I have a stove and everything is being destroyed by woodlice. They are destroying everything, and the more I destroy the more seem to come. Can any of your readers advise as to the best way of getting rid of these pests?—LEES.

Theropogon pallidus.—This is a pretty little plant from the Himalayas, that will grow and flower well in an ordinary greenhouse. It forms a dense clump of grass-like leaves—indeed it bears a considerable resemblance to an *Ophiopogon*, while the blooms are much like those of the Lily of the Valley, not only individually, but also in the way

in which they are borne. The flowers are of a pale purplish hue. When seen in the shape of a specimen bristling with flower-spikes, it is both an interesting and a pretty plant.—H. P.

SEASONABLE WORK IN PLANT HOUSES.

AMARYLLIS.—The cultivation of these fine bulbs promises to become as general as at one time it was exceptional. The present race of Ackermann and Leopoldi hybrids are better growers and more certain bloomers than the species and varieties of these plants that used to be within the reach of ordinary cultivators, and when once a few really good varieties are obtained the means are at hand for securing seed, from which, at the least, varieties that are quite good enough for decoration may be relied on. For though with *Amaryllis*, as with most plants that cross freely, new kinds that surpass the best already in existence are not to be looked for as an everyday occurrence, still there is this in favour of seedling-raising with the plants in question, that where there is the opportunity of saving seed from good varieties the seedlings forthcoming may collectively be reckoned upon as good enough for decorative use. Where it is desirable the time of *Amaryllis* flowering may be accelerated or retarded considerably so as to have them in succession, but in most cases the bulbs that have flowered latest will now shortly be out of bloom and be making their growth. During this time intermediate warmth suits them better than either a high temperature on the one hand, or ordinary greenhouse treatment on the other. To do justice to the plants they must have plenty of light; short, stout, leathery leaves are essential to the bulbs attaining the full amount of strength. Through the growing season the syringe should be used daily; without this red spider is likely to be troublesome, and the presence of this little pest is highly injurious, as if it is allowed to get ahead it invariably causes the foliage to lose its vitality sooner than it should.

IMPATIENS HAWKERI.—In appearance, so far as habit of plant and the form of the flowers are concerned, this new sort is much like *I. Sultani*, but the colour of the flowers is different and much more telling than the older kind. It is more than likely that *I. Hawkeri* will be found one of the most useful plants for the decoration of greenhouses and conservatories that has appeared for some time. Its easy propagation and the quickness of its growth are much in its favour; the smallest bits when newly struck and potted off will flower, but, like all quick-growing subjects that are soft and fleshy in their shoots and leaves, the plants must from the first be kept close to the glass in a light house or pit so as to keep their growth stocky and short-jointed, as if at all drawn the flowers are fewer and the whole appearance of the plants indifferent. Plants of this *Impatiens* if wanted to be grown up to a considerable size only require proportionately larger pots and more head room, but in most cases small or medium-sized examples will be the most serviceable. To keep up the requisite stock a few should be struck at intervals all through the spring and summer. The plant is said to come from the South Sea Islands, and as such, in common with other things that hail from the same quarter, will require to be kept warm in winter and spring, but it frequently happens that plants that will not do without warm treatment in the dormant season and during the early part of the growing period will bear a greenhouse temperature from midsummer until the nights begin to get cool, provided they are not subjected to cold draughts through being carelessly placed near where air is admitted. Not unlikely this beautiful Balsam will stand a temperature of this sort in summer, in which case it will be doubly useful.

JASMINUM GRACILLIMUM.—It necessarily follows that large, full-grown examples of this charming plant, such as are obtainable by turning them out in a bed, will yield the most flowers, but to ensure a succession a sufficient number of medium-sized plants are better than one or two large specimens, especially when they are grown in pots, so as to admit of their being placed in more or less heat as becomes necessary. Young plants that

were struck from cuttings early in the year should be pushed along in a brisk-growing temperature, moving them into larger pots as these are needed. Stop the shoots so far as necessary to ensure the plants being fairly furnished with side branches, for, though more inclined to a bush-like habit than others of the genus, still, if left to itself, the growth is thin and straggling. Keep the plants well up to the light, giving a moderate amount of air in the middle of the day, with a thin shade when the weather is sunny, so as to get the benefit of that warmth after the lights are closed and the blinds run up, accompanied by a moisture-laden atmosphere. The growth that is made by the plants in a house that admits plenty of light in the two or three hours that follow closing in the way indicated is worth all that they make in the rest of the twenty-four hours. T. B.

FLOWER GARDEN.

PRIMULA SIEBOLDI.

THE editor regrets that this beautiful Primrose is not more usually seen in gardens planted out. Whilst sympathising in that expression of regret, I may add that I feel some surprise at not seeing it generally grown as frame plants in pots for greenhouse decoration also. Outdoors, in good sandy soil, such as rock plants, and specially Primulaceæ delight in, Siebold's Primrose should do well, the chief requirements being good drainage, deep cool soil, and some shelter from winds. No doubt the herbaceous habit of the plant militates against its outdoor cultivation, because when the foliage is gone it is out of sight, and soon out of mind. It is worthy of trial, however, whether plants kept in pots in cool frames during the winter would not turn out well in the spring before the bloom-stems were up. In snowy or mudly rainy winters the crowns suffer from excessive moisture, and being so close to the surface are in more danger than are those of many other things. But if some little care is needful with this Primrose, some ample reward is found for good culture later, no matter how conducted. Nice pots or clumps of Sieboldi, or of its progeny *Hermia*, blue; *grandiflora alba*, or *Snowflake*, white; *laciniata*, red, and many others, are indeed lovely both in foliage and flower. I think the flowers of *laciniata* present most acceptable matter for bouquet making or vase decoration, the colour of the flowers, under artificial light, standing out with striking effect. If grown for exhibition I should like to see them in 12-inch pans, but for that purpose the grower should have an ample stock of each kind from which to select some two dozen or so of the strongest rhizomes or crowns when dividing them in the autumn. Such pans well looked after would give almost masses of beautiful flowers set in a bed of handsome foliage, and thus become for the time literally the handsomest of all exotic Primroses. I prefer pans to grow the crowns in for the purposes of propagation, because in these they find more room, have ample soil depth, hence less pot-area exposed to the sun and wind, and are easily watered. Of course, in breaking up the pan clumps in the autumn, it is easy to select the best crowns for special pot-culture, whilst all the weaker crowns can be replaced in pans in fresh soil for further development. A cool frame and an ash bottom seem essential requisites for successful culture in pots or in pans. I must apologise to Mr. Douglas for not having made myself conversant with the change in the *Auricula* show class devoted to Primula species. I consider the change in shutting out two plants or more of some of the most showy or effective of Primulaceæ to have been a mistake. Of effective forms I name specially Sieboldi and its varieties, *obconica*, *floribunda*, *japonica*, and a few others when well done; then *denticulata*, *cashmeriana*, and lots of others having small flowers may be termed pretty; whilst *scotica*, *minima*, and similar pignies may well come under the head of microscopical, as their charms can only be found upon close inspection. In making up classes at flower shows for the gratification of the general public

effective kinds only should be chosen, but for botanic purposes no doubt the minute-flowered kinds have exceeding interest. In the case of Primroses and Polyanthuses in pots, Mr. Douglas would perhaps hardly desire to see collections of wild varieties, because they would give so little that was beautiful or attractive. A. D.

THE LAYIAS.

THIS highly ornamental genus of annuals, natives chiefly of California, has now been made to include a number of plants well known in gardens at the present time under other names. The Layias, without exception, are a class of annuals that should be included in every selection, as well for their neat habit of growth as for their beauty and free-flowering character. They commence to bloom soon after the beginning of summer, giving a continuous succession until autumn. Most, or perhaps all of them, are of a more or less trailing habit of growth, and when grown in large patches have a very striking effect. Where exposed to winds, &c., the plants should be tied to a few short stakes or pegs to keep them steady. Few annuals are more use-

Layia elegans.

ful for covering permanent bulb beds or patches of bulbs in the mixed border. They can be sown in the open air about the end of March or beginning of April, and give little or no trouble, except thinning out where they are growing too thickly. We have also found them extremely useful as cut flowers.

Amongst those grown in gardens at the present time, *L. elegans*, represented in the annexed cut, takes a first place. It belongs to the same section as *L. glandulosa* and *L. heterotricha*, to both of which, indeed, it is very nearly allied. It grows about a foot or so high, compact, bushy, producing in profusion throughout the season its handsome flowers. The ray florets are of a fine soft yellow, tipped with white.

L. glandulosa, recently introduced, is a very handsome kind, in habit and other respects resembling the above, but with pure white flowers $1\frac{1}{2}$ inches in diameter. *L. platyglossa*, known as *Callichroa*, light yellow, with whitish tips; others, such as *L. Douglasi*, *chrysanthe-*

moides, *calliglossa*, &c., are all distinct enough to claim a place in the border devoted to annuals. They all ripen seed freely. K.

SPRING FLOWERS AT PANTON, BERWICK-SHIRE.

The soote season, that bud and bloom forth brings,
With green hath clad the hill and eke the vale.
LORD SURREY.

THE most enjoyable period of the year is approaching, for the Larch has assumed its mantle of tender green, and the earliest buds of the Beech, Chestnut, and Plane are bursting into leaf. In the mornings and evenings the woods and groves resound with the voices of many birds, amongst which may be heard the flute-like notes of the blackbird and the mellow strains of the thrush, intermingled with the joyous and oft-repeated songs of the chaffinch and the willow wren. At intervals the chorus is joined by the blackcap, which has now returned from the south, and is varied by the soft cooing of the cushat and the cawing of the rooks at the distant rookery.

Nature inanimate employs sweet sounds,
But animated Nature sweeter far,
To soothe and satisfy the human ear.

The most favourable time to walk in the garden amongst the spring flowers is either on a fine calm morning, when the dew with which the plants have been refreshed during the night is still on the grass, or on a quiet evening when the sun is getting low and shedding its mellow light through the trees. Then the delicate colours of the alpine plants can be seen to perfection, for when the sun is high and pours down a flood of light, the soft tints of these flowers are partially obscured.

Spring flowers have the best effect when they are grown in large clumps, and on this account it is desirable to save seeds from as many kinds as possible, so that they can be raised in quantity and numbers planted together in one spot. While referring to this subject it may be mentioned that the introduction of a hive of bees to the garden has a perceptible effect in causing many spring-flowering alpine plants to produce seed which would not otherwise do so.

The weather for the last few weeks has been very changeable and unfavourable for spring flowers, which have suffered much from frost during the night and the cold east wind during the day. Hail-storms have likewise been frequent, reminding one of the lines of the old Scottish poet, William Dunbar—

Yistirday fair sprang the flouris;
This day that ar all slane with shouris.

But, notwithstanding the ungenial weather, a great many spring flowers are now coming into full bloom; and although most of the Narcissi, such as *Horsfieldi*, *maximus*, and others, are going past, their places are being taken by others, amongst which may be mentioned the Duchess of Westminster, *J. B. M. Camm*, and several of the poetical section, including *p. ornatus*, which is one of the finest. On the rockery *N. juncifolius* and *N. muticus*, from the Pyrenees, are in full flower, as well as various white Daffodils, *N. cernuus plenus* being conspicuous for its lasting qualities. Several kinds of Muscari may be seen flowering amongst the stones, including *M. atlanticum*, *Heldreichii*, *moschatum*, *neglectum*, *Stenacheri*, and *Szovitzianum*. One of the most distinct and lovely flowers is *Fritillaria Meleagris alba*, and near a clump of it are to be seen *F. pallidiflora* and *F. armena*. The rarest alpine at present in bloom, however, are *Androsace villosa*, which is like a little grey cushion covered with white stars, and *A. ciliata*, a somewhat similar plant, with rosy crimson flowers, and which is described by Baekhouse as "one of the most beautiful of all the Androsaces yet discovered." The Androsaces above mentioned are from the Pyrenees, and were procured through the kindness of a lady in the county who lately visited these mountains. *A. carnea* and *A. Lagerri* are likewise in bloom. *A. glacialis*, of which there is a large tuft, has not yet flowered. A fine early *Veronica*, from Froebel & Co.,

is *V. satureifolia*, which is at present covered with its blue flowers.

G. MUIRHEAD.

Paxton, Berwickshire.

RAIDS ON WILD AND OTHER FLOWERS.

MR. COLEMAN'S timely and vigorous protest (p. 415) shows that these raids still continue. They are alike antagonistic to the spread of botanical knowledge and the development of some of the most alluring features of semi-natural landscapes. The raiders are little better than robbers, whether dressed in rags or in broadcloth. If anything the latter are the more bold, and difficult either to restrain or punish. It is many years ago since my early attempts to multiply summer plants in a wholesale way in pleasure grounds and woods were checked and partially frustrated by the wholesale pilferings of plant stealers. Enormous quantities of Snowdrops, Daffodils, Primroses, Forget-me-nots, Windflowers, Valley Lilies, &c., had been propagated, put out, and partially naturalised. So far, everything promised the success of wild gardening on a large scale. The object was twofold—to link formal on to natural gardening through these and other plants, as well as to light up the home woods with a prodigal wealth of beauty and of fragrance. Hardly, however, had the birds and rodents got used to the new garniture of their homes and agreed to let the strange plants alone—and this takes some time—than the raiders began their work of destruction among the flowers and plants. Seas of golden Daffodils that rippled with golden-crested waves to-day were found flowerless on the morrow. Great groups of Valley Lilies that filled the demesne with fragrance one day, were scentless, because flowerless, the next. And a similar fate awaited Snowdrops, Golden Aconites, Windflowers, Primroses, Wood Hyacinths, Tulips, wild Orchises, &c., &c. The flowers were stolen in handfuls, basketfuls, barrowfuls, cart and carriagefuls. Yes, incredible as it may appear, one of the first thieves caught was a lady, who had ordered her carriage to stop on the outskirts of the home woods, got in, gathered quantities, and was just off with a load for some church festival when caught in this act of sacrilege.

Wild flowers! Surely these are free to be plucked, or torn up by the roots by all. Such is the popular fallacy which pervades high and low in many parts of the country. And hence it is not the flowers alone that are taken, but the plants likewise. Men and women come in fustian and broadcloth, cottons and silks, with bags, sacks, baskets, and barrows, spades and trowels, pounce upon, dig up, and carry away one's favourites. Again and again has our wild garden been impoverished and marred by these impudent marauders and thieving raiders. Huge groups and patches of uncommon and common types of Primroses, including *P. japonica*, Snowdrops, Daffodils, Narcissi, Forget-me-nots, Daisies, wild Orchis, Peonies, Anemones, &c., have been subjected to such heavy raids until few have been left. Few things are more discouraging than these cruel raids on our favourites, and there seems no sufficient remedy. Catch the raiders in the act, and abuse or an apology, according to the status or character of the offenders, is all you will receive. Unless you are very firm indeed there will be no word about restitution, nor the slightest chance of recovering your property. I caught a lady once who added a huge basketful of choice *Rhododendron* blooms to her other booty, and though I saw her off the grounds with not a few remonstrances, she kept fast hold of her booty and walked off with it.

Neither the morality of the classes nor the masses recognise any right to the possession of so-called wild flowers, nor of garden ones that the taste or genius of the cultivator may have increased to such an extent as to be massed with them in woods or wild gardens; and the law does no more for their protection than public sentiment or morality. Our legislators have passed laws to protect not a few beasts and birds and fishes, some of them of very questionable utility, such as hares, rabbits, chaffinches, and sparrows, and it might hardly be too much to request them to protect our wild flowers

from the attacks of those wholesale raiders who, either from mere greed or the love of gain, are threatening them with destruction in many quarters.

There are also other ways of destroying semi-wild flowers besides stealing them root and branch. The annual removal of their flowers and foliage in a rough manner or at an unseasonable period and the trampling down of their leaves, as described by Mr. Coleman, result in growing weakness, sure disease, and certain death. Pity it is that the public cannot go, see, and admire natural beauty as they do fine pictures and perfectly chiselled sculpture without dreaming of becoming the possessors of the masterpieces of either Nature or art. The mere craving for possession is as vulgar and selfish as it is suicidal. Within the domain of art it can only be gratified by sacrificing the pleasures of the many to the gratification of the very few. In the field of Nature each flower and plant-grabber leaves the landscape so very poor, that finally the fair face of Nature is stripped bare of all its beauty, and thus the charms of our natural or semi-natural landscapes are totally destroyed.

One of the most potent causes of this wholesale destruction of plants and flowers is founded on the exaggerated importance attributed to mere mass or numbers in decorative arrangements. That mass is might, has long been accepted as an axiom in science. Not this, however, but the exact converse is true in matters of taste—the lighter the touch, the more sparse the material, the more exquisitely beautiful the room, church, hall or table arrangements as a rule. And yet we see carriage and cartloads of flowers and foliage crowded into our churches, public buildings, and houses at Christmas and other festivals, dinner parties, balls, and harvest thanksgivings, and to get these masses together, meads, woods, pleasure grounds, gardens, glass houses are stripped bare. The results, as might be anticipated, are very much as if the artist were to exhaust his paints on the canvas and craze for more as the *siue qua non* of his masterpiece. And so under or over some of the most pretentious floral decorations it might be written, the more prodigal the waste of flowers the greater the paucity of taste. An infinity of time, labour, material have been wasted, woods, gardens, meads stripped bare, and the results, artistically like that of the artist who should exhaust all his colours on his canvas, worse than nil. Instead of beauty there is deformity, the legitimate product of grasping greed, vulgar display, and vitiated taste. No wonder if the ponderous table decorations prove more fruitful sources of nightmare than the lateness of the dinner or the richness or abundance of the viands. — D. T. F.

— I have been surprised to read Mr. Coleman's account (p. 415) of the damage done by the public to trees and flowers in his parks. Ladies and their children taking the liberty to "load their carriages" with flowers and Hawthorn "unmercifully torn from the trees" is, I admit, sufficient to cause any gentleman to shut his gates on the public for ever, but I hope and believe such practices are quite exceptional, and one would not expect to hear of such vandalism among the more rural population of the south, where the "masses" are supposed to be more mild-mannered than they are in the north. Hereabouts, where we have to deal with scores of thousands of "trippers" from the so-called worst districts of Lancashire and Yorkshire (colliery and manufacturing), to whom one of the largest woods and parks in England is open throughout the year, I must say that nothing has ever struck me more than the general good behaviour of the visitors, especially of the working classes. I may say that we never call in the aid of the police, and a summons for damage or trespass I have not taken out for nearly three years. Any watching needed our own woodmen do, but their orders are not to be officious or intrusive in any way; no watchers are employed except on great gala days, when many thousands are scattered over the park and wood-drives, and where there are much game and deer near. Yet when the Bluebells, the Hawthorn, and other wild flowers are out, and numbers of beautiful wild Ferns growing everywhere, you may walk two or

three miles from any of the stations through the wood, meeting a steady stream of people all the way, on foot or in carriages, and not one with a flower or twig in their possession. What we fear most is fire to the dry Brake, caused by occasionally careless smokers. Otherwise, the public seem to realise and appreciate the privilege of free access, and do their best to preserve it by assisting to promote order and good behaviour on all occasions. I notice even that when the Blackberries and Blaeberrys are ripe and temptingly within reach, it is rare to find any visitors going off the drives and footpaths to gather them without permission. The whole parks are studded with Hawthorns, many of them much valued on account of their age, but if they were to be as unmercifully torn to pieces as Mr. Coleman's are, they would soon disappear, and the wonder is that where such things are so unwisely tolerated, that has not happened long since. — J. S. W.

Primroses, single and double.—Will some of your correspondents kindly tell me the right time to sow Primrose seed, the after treatment of the plants, and how long after sowing the seed it will take to establish them so as to have nice sturdy specimens that will throw up fine spikes when planted for spring bedding. They are wanted to flower early so as to be taken up after flowering to make room for summer bedding. I may say that they are required to be planted in a very exposed situation where we get the full force of easterly winds, and where two-thirds of double Daisies and Forget-me-nots are completely killed each winter with the cold and frost. Also what is the difference between the climate here and the south of Devon, where Primroses flourish planted out in autumn for flowering in the spring? — R. G., *The Gardens, Coldra, Monmouth.*

Border Auriculas. These are now in fine bloom, and the wonder is that they are not more generally grown, for they are as hardy as the Primrose and the colours are rich and varied. They are capital subjects for lifting when in bloom, as, if carefully done, they will not drop a leaf, and as soon as the flowers fade they may be planted out again. We grow them on borders close to a wall, where the soil is light and dry. By putting on a good dressing of manure when they are divided and replanted after flowering they make luxuriant growth, and flower profusely every year. They are also subjects that do well in towns, for even in the narrowest streets and most unlikely places for finding healthy plants one frequently comes across a windowful of really good Auriculas, that not only live, but thrive and increase, and are much prized by the owners. The best way to get up a stock of varied colours is to buy a packet of seed, sow at once, and keep moist until the seedlings are large enough to prick off into pots or boxes, and keep them in a cold frame through the first winter, and in April prepare a nice piece of soil and plant out 1 foot apart each way. Keep the soil stirred frequently and water freely in dry weather, and little other care will be required until the following spring, when they will push up very strong flower-spikes, and may be lifted carefully and potted at once. Give a good soaking of water to settle the soil and shade from bright sunshine. The perfume from these lovely flowers is most agreeable, and I feel sure that if owners of gardens could get over the idea that they need pot culture all the year, they would be much more grown than they are now. — J. G., *Hants.*

Aubrietias. In some notes on hardy plants, "K." alludes to *Aubrietia Leichtlinii* as the deepest hued variety. I saw this kind in bloom in the Kew collection of hardy plants at the Auricula show and thought it represented exactly a seedling form of violacea such as I have here in quantity, and not mere small pieces in pots, but large clumps or masses blooming with wonderful profusion. *Violacea* and its progeny, curiously enough, however, show just the obverse character to *A. Leichtlinii* in respect of the fact that, whilst the latter is said to make its blooms fade with age, those of the former invariably deepen in colour with age, and yet growing out in

the open without shade or protection. What blue Lobelias are in giving a mass of colour in the summer, a violacea is in the spring; indeed, whether in beds, borders, or on rockwork open to the sun, these deep-coloured Aubrietias are wonderfully effective. Whilst purplish violet is the prevailing hue of the flowers of violacea, some of the seedlings give a distinctly reddish or approaching to maroon tint. I think by determined selection it is possible that in time we may have a genuine bright red-flowered Aubrietia. Nothing seems to distress Aubrietias more than lifting and dividing them, but, of course, that work must be done sometimes, and is best done in October. The plants are, however, wonderfully recuperative, for I have seen them, after being apparently half killed by the winter, break up densely from the roots and make large clumps. My plants are blooming this year later than usual partly for that reason, and partly because all hardy plants are blooming late. It cannot be too well understood that Aubrietias come freely and true from seed.—A. D.

Daffodils.—One feels almost a sense of relief in the knowledge that the Daffodil season is nearly over. Under ordinary circumstances it is easy enough to keep out of the reach of the craze by growing a few of the best kinds only, and those as ordinary hardy garden flowers. But those compelled to attend the London spring shows, and those at South Kensington especially, cannot repress a sense of intense uneasiness, deepening into disgust, at the repetition time after time of long lengths of Daffodil flowers duplicated *ad nauseam*, certain exhibitors seeming anxious to excel each other in the extent of their displays. That this soon becomes intensely wearying and monotonous is evident, and it is feared must tend to keep away visitors who cannot endure so much of the Daffodil colour. It is difficult to see what possible good to the gardening world can result from all this hair-splitting and refining, whilst the most useful intelligence to ordinary gardeners, viz., a list of a score of the very best kinds for all ordinary uses, seems to be withheld. If M. de Graaff has many more to follow of such fine forms as those which he exhibited on the 10th, not a few of the fancied kinds now seen so abundantly at South Kensington will soon be ousted. It was amusing to note that whilst the Daffodil committee were gravely discussing some knotty point as to breadth of trumpet or scape, the floral committee should have voted two or three first-class certificates to M. de Graaff in as many minutes.—A. D.

— I still adhere to the opinion that in order to flower the tenderer Daffodils to perfection in a cool soil and climate, we must plant the bulbs shallow; deep planting produces growth, but no flowers, comparatively speaking, and I have now no doubt of this from actual experience with the best sorts. I leave theorists to reconcile the facts, but of this I am certain that in cool places and soils deeply planted bulbs flower but sparingly, if at all, and *vice versa*. What, by the way, is the experience of your readers with Daffodil Sir Watkin? I bought a few of the first flowering bulbs from an undeniable source and they have bloomed well, but for size and show the flowers are utterly eclipsed by Daffodil Horsfieldi, which, with its grand foliage, large and conspicuous flowers, ought to head the list among the yellow Daffodils. It has many good qualities, being a good grower, hardy, and one of the very freest bloomers anywhere. It stands out among all others wherever grown.—S. W.

Wild and garden Primroses.—Growers in the south evidently do not know the capabilities of the common Primrose under all conditions, or they would not write of it being the "weakling" of the family, and of its inability to face the sunshine. Hereabouts in a cool midland climate, and in many other places where I have seen the wild Primrose growing in England and Scotland, it flourishes on open sunny banks and in grass fields, as well as in the woods; but it is under garden culture you see it at its best, and where roots two or three years old produce flowers in great profusion. Young plants two or three years old, I admit, do best, but I have stools from five to nine years old on the grass

and thousands that have been divided and redivided, for we have them almost by the acre on the grass and borders and all the very best strains, as well as the wild Primrose, which is undoubtedly the most vigorous and hardy of the lot. The varieties are endless and the colours superb, and you cannot plant too many; keep dibbling in and you will have your reward. Our older plantations are ablaze with flower, and we have not long sown our annual bed of wild Primroses on a sunny border. As to the wild Primrose, you never see a big plant of it wild; they are all small and none appear to grow old, but in the garden they live and grow like Horse Radish, making leaves nearly 1 foot long, and flowering in proportion.—J. S.

FANCY AURICULAS.

THE fancy Auriculas, as they are termed, appear likely to form a permanent place in our Auricula exhibitions. Raisers of seedling Auriculas of the show type are aware that among their seedlings will appear some of such nondescript character, as to prevent their being placed in any one of the four sections of show varieties, and yet they are far too good to be thrown away. Thus we get edged flowers which, instead of having the black or violet body colour found in the green, grey, and white-edged sections, are golden, with gold overlaying the grey edge, or buff; or they may be self-flowers, but having shaded edges, as in the case of the alpine. Many of them are extremely pretty, as was shown by the collection with which Mr. J. Douglas took the first prize at the recent Auricula show. Now, the self Auricula of the florist must not have a shaded margin; it should be of one distinct tint of colour, and in this respect be unlike the alpine varieties, which should properly have shaded margins. Thus it is that if self Auriculas come with the golden tube and circle of white paste, and beyond this a distinctly shaded instead of a self-coloured margin, it must go into the fancy class. I am taking the rules of the florist as they are, and so long as they are recognised they must be respected by exhibitors. Thus it is that I am trying to show what is meant by a fancy Auricula. I have this season raised several nondescript forms that are highly attractive, and will go under the head of fancies. The term "fancy" has a wide application, because the pretty faced varieties as well as the double Auriculas can be shown with them.

I have said that the self show Auricula should be one-coloured, anything in the way of distinct shading being considered a disqualification. I have also said, in contradistinction to this, that the alpine Auricula should have a shaded margin. At the Auricula shows in the north of England a self-coloured alpine Auricula (and Mr. Turner has raised and put several of these into circulation) is put aside, and shaded forms preferred. That is the old rule in relation to this class of flowers. But in the case of the Auricula exhibition held in London, self-coloured flowers are admissible, and are shown and awarded prizes. I have shown Mr. Henry, Colonel Scott, James Fowle, and other unshaded flowers, and taken prizes with them. It is a little curious that the northern and southern practices should differ, but so it is.

It is sometimes said that the florists lay down hard-and-fast lines of arbitrary character. If a body of floral enthusiasts like to unite together and lay down certain recognised laws, under which they exhibit their flowers, they have a perfect right to do so. That an adherence to these laws on the part of raisers has resulted in greatly improving our show Auriculas, there can be no doubt. This was made abundantly evident at the exhibition on the 26th ult. Such a heritage of new flowers as we have seen during the last four or five years was never before bequeathed to one generation, and not a few of the older flowers must of necessity fall out of cultivation in consequence.

R. D.

Anemone coronaria.—When this Anemone is treated as an annual (and this is the best way of growing it), there must be no further delay in sowing the seed, otherwise the plants will be too weak

to flower during the winter, and when sown it must have regular attention in the way of watering in order to induce quick germination. For this reason I like to sow the seed in boxes and to place them in a cold frame until the plants are large enough to bear transplanting, and it is surprising how well they do after they are planted out. One reason for this is, I think, that the plants have more room, as when they are sown where they are to flower they come up in bunches owing to the difficulty in separating the seed. When the plants are raised under glass they should be about 2 inches high before they are moved; they will then lift with a good number of roots, and if they are put out in dull or showery weather they quickly take hold of the soil and make vigorous growth by the end of October. The past two winters have been too long and too cold for them even in the west of England, but in moderate winters they do well and amply repay for the labour they involve. When the seed is sown in the open it should be sown in drills 1 inch deep and a foot apart, and to assist the seed to germinate the bed should be shaded in some way. This covering must be removed as soon as the young plants appear. Where they come up too thick, they should be thinned out as soon as they are large enough to handle. Where these plants are expected to flower during the winter and early spring, the bed requires to be in a warm position. A south border sheltered by a high wall is the best place they can have.—J. C. C.

Primula nivea.—Of all the hardy species of Primulas, I find *P. nivea* the earliest to flower. I grow some specimens in 1½-inch pots that come into flower in my Auricula house almost as soon as the quickening influences of spring are felt. As soon as the plants go out of flower, they are divided and repotted into small pots and plunged in a bed of Cocoa fibre for the summer. If I want a few extra sized specimens, I cut away the shoots near the surface, and these make excellent cuttings; the plants soon break into numerous shoots, and when repotted they grow fast, and make capital specimens by April. I have never yet succeeded in seeding this little gem. I have tried fertilisation of the flowers both with its own pollen and that from other allied forms, but as yet without success. All lovers of spring flowers should find a place in their gardens for this lovely snowy Primrose.—R. D.

Sparrows and flowers.—I send herewith the heads of Primroses as picked off by the sparrows. When they do attack a plant they generally do not leave a single head on it, and the bare stalks and leaves are all that are left. I have not observed this attack on Primroses before this season, though they have attacked Crocuses, but not so badly as some have complained of. Can any reader suggest a remedy? An iron collar round the plant has hitherto saved them from attack.—CHAS. WM. COWAN.

* * * Sparrows are an unmitigated nuisance in more ways than are generally suspected. Apart from their destruction of flowers they drive away the more beautiful insect-eating birds. By bat fowling, and in every way, gardeners should do their best to reduce the numbers of sparrows. Their nests made about garden buildings and houses should be regularly destroyed. Mr. Cowan sends us a box of Primroses which have been nipped off by these pests.—ED.

Old r. young Wallflowers.—That the winter has left its traces upon these there can be no doubt. We grow a great many here annually, and I had a lot of two-year-old plants in different positions in the garden, and the frost has completely destroyed them. Fortunately, in the flower garden proper I had only young plants, and scarcely one of these has failed, but, on the contrary, both the plants and individual blooms are extra fine. I always sow the seed in the first week in May on a well-prepared seed-bed, and prick them off as soon as large enough, a foot apart each way, and keep a sharp look-out that they do not suffer from want of water, else they lose all the bottom foliage, and they are then anything but fit for a flower garden. So managed, they make good plants by the end of October, at which time they will be ready to be transferred to the positions in which they are intended to flower.

taking care to press them firmly into the soil. There is nothing, to my mind, more charming now than these flowers. Beds of yellow, edged with *Myosotis*, and the Blood-red, with edges of the white and variegated *Arabis* are simple, yet the effect produced is grand and the odour delightful. I am quite aware of the extra work it entails, and how the soil is robbed, but these little difficulties are always easily got over and soon forgotten by the energetic and interested operators.—W. A. Cook.

Venus's Fly-trap (*Dionaea muscipula*).—This ought to find a place in every collection of hardy plants as well for the beauty of its flowers as for their curious appearance. In the neighbourhood of London, where the climate is not one of the most genial, this plant has stood out in the open air for a number of years, with only a broken bell-glass over it, and this has been used more as a protection against birds than against frost or cold. In the summer it sends up in long succession its numerous spikes of large white Saxifrage-like flowers. It is growing in peat in an artificial bog bed, and appears perfectly at home. Every second year it is lifted and divided, the plants being dibbled in singly, as the frost has a tendency to push them out of the soil owing to their shallow roots.—K.

Crimson velvet double Primrose.—This king of all the double Primroses does well in Mr. Samuel Barlow's garden, at Llandudno, planted out on a turf bank facing the north. It is a cool and moist position, and this and other choice Primroses find a congenial home there. A hole is dug out in the bank, the Primroses are then planted with suitable soil about the roots, and there they have established themselves, kept cool by means of the Grass which grows up around them. But that some of the choice double Primroses are delicate is a fact; even such a successful and enthusiastic gardener as the Rev. F. Tymons, who grows a large representative collection near Dublin, terms some of them "miffy." Possibly this is owing to the fact that certain sorts are very scarce, and have to be propagated severely in order that the necessary stock for sale may be obtained. The method of planting out permanently is a good one; in this way the varieties can recover constitutional vigour, and in course of time form offsets, and so propagate their kind. But only a few have the convenience for doing this.—R. D.

Tulipa Greigi.—This is the showiest and most striking of all the species of Tulips we have yet seen in cultivation, and although it is said to be somewhat shy in blooming, it fully makes up for this deficiency by its unusually large and handsome flowers. I think it is one of those Tulips that should be left alone as much as possible, as it does not flower until the bulbs have assumed a fair size. A light, rich, sandy, and well drained soil seems to suit it best; in plenty of sunshine and about mid-day when the flowers are full open it looks more like a *Paeony* than a Tulip. The segments are about 3 inches long, and rather more than half as much broad, vivid red, with a black blotch near the base. Even when not flowering it may readily be known by the black blotched or spotted leaves, which are so unlike any of the other garden species. It will soon become plentiful, as we saw it the other day growing freely in a market garden.—K.

Laced Auriculas.—Mr. Douglas is kind enough to refer to me as having introduced and improved laced alpine Auriculas, but having now dropped them, the first part of this statement is correct; the latter is not so. We have simply given over any attempt to name and divide the best kinds, because it is found easy to perpetuate good strains through seedling, and seedlings are easily raised. Did circumstances permit, I should prefer to sow seed as soon as ripe, as I do *Polyanthuses*, and house the young plants in frames during the first winter. By so doing really strong-blooming plants would be assured the second spring. As it is, I sow under glass in April and now have hundreds of seedlings, but they grow slowly, as do all Auriculas, and will hardly be ready to dibble out into the open ground for another month. A large number of plants, carrying several crowns, are blooming now in the open field, and display as perfect markings as if in

pots; but, of course, under hot suns and parching east winds such as just now prevail, can hardly preserve their flowers so long as could be wished. That is, however, more an accident than otherwise, because these large plants were all replanted during the winter, whilst another lot of border or self alpines, left unrenewed, blooms profusely. If the Auricula Society continues to exist, I trust it will be able soon to establish a special class for half-a-dozen laced alpines, and thus specially encourage one of the most charming sections of Auriculas. It is evident that until such is the case little encouragement is given to naming and propagating the best forms. Mr. Douglas refers to the self-coloured alpines as self-edged—a curious combination of terms. The colour in a self alpine is the ground, and as it is the same throughout it is not edged. Really in alpines the only edged flowers are the laced section, the edges being clearly defined and very distinct from the ground.—A. D.

SALES OF HOTHOUSE PRODUCE.

MESSRS. J. W. DRAPER & SON write as follows: Up to the present we regret that the introduction of English cut flowers and fruit to our Public Auction has not proved a success, the main reason being the entire lack of judgment and system in packing; a regular report as to the current rates of home produce of this class is therefore scarcely practicable. We included such goods merely as an adjunct to our auction sales of French and other Continental consignments, and without any idea of great emolument; we feel, however, that the absence of method and care on the part of the English senders is somewhat discouraging. We have sent several the following hints. If these are carefully studied and carried out, we may hope for better results in due time. To-day we sold best English Strawberries, packed in accordance with our directions, at 4s. 6d. per lb.

SALE DAYS.—The sale days are Mondays, Wednesdays, and Fridays. Goods should be sent for these days only, and despatches so regulated that consignments arrive prior to 10.30 a.m., at which hour our sales commence.

PACKAGES.—Neat wooden boxes (shallow rather than deep) of uniform size to be used. One kind of fruit or flower to be packed in each box. Mixed or miscellaneous packages seldom do well. N.B.—The boxes are sold with the goods, and are not returnable.

PACKING.—Choice flowers, such as Roses, Gardenias, Camellias, &c., should be carefully selected, not too fully blown, and packed between sheets of wadding in single layers, i.e., a single layer only in each box. At all times it is necessary that particulars of the number of flowers in each box be marked on the lid, or on a slip of paper under the lid. Strawberries, Peaches, and other indoor fruits should not be sent in punnets, but be sorted, as to size, and placed carefully in single layers in shallow boxes, a sheet of wadding over and under, so that damage through friction or oscillation may be obviated. Separate boxes properly marked with finest selected and seconds ought to be sent; the price given for the first-named generally pays for the trouble of grading. As with flowers, a slip of paper with weight or number must be enclosed. Special attention is called to this. To save expense in carriage and for convenience in travelling two or three boxes may be corded together so as to form one package.

ADVICE OF CONSIGNMENT.—Postal or (if too late) telegraphic advice of each consignment should be sent; when this is neglected trouble and complication often ensue.

To ensure success it is requisite that the above details are carried out. After the primary trouble the system becomes easy, and the advantage of method will be appreciated.

Plants for bees.—In answer to J. Smith, who inquires as to the above in THE GARDEN April 23 (p. 370), the following will be found useful plants to grow: Mignonette, Wall-flowers, *Arabis* of sorts, *Sedums*, *Crocuses*, *Hyacinths*, *Cine-*

arias, single *Primroses*, single annual *Chrysanthemums*, *Larkspurs*, *Musk*, *Heaths* (hardy varieties), *Sweet Williams*, *Narcissi*, *Stocks* (single), *Corn Flag* (*Cyanus*), *Nasturtium*, *Candytuft*, annual *Phloxes*, *Heliotropes*, *Borage*, *Clarkia pulchella*, *Nemophila insignis*, *Aubrietias*, *Poppies* of sorts, *Gilia tricolor* (various) and *alba*.—R. G.

GARDEN FLORA.

PLATE 597.

LIMNOCHARIS HUMBOLDTI.*

WE have not many water plants that equal this pretty floating *Limnocharis*, whether considered as a fit companion for Water Lilies, *Nelumbiums*, and such like large aquatics, or as a suitable and easily managed plant for small aquaria. Treated liberally and allowed plenty of water room, it soon covers a large space with a carpet of disc-like shining green leaves, thickly studded with bright yellow blossoms; in tubs, large bell-glasses, or small tanks it is equally happy if allowed plenty of sunshine and a temperature of about 70°. The most valuable point about *L. Humboldtii* is its never being out of flower if only allowed to go on growing. At Kew it may be seen flowering all the year round, and along with the Water Lilies it is specially attractive all the summer through. It is impossible to reproduce on paper the attractions of this plant, but the beauty of the flowers are shown. These are very fugitive, opening in the morning and withering before the day is over, but they are developed so abundantly and in such quick succession that this is scarcely noticed. Wherever tropical water plants are grown this *Limnocharis* should find a place.

There are only three or four species known, two of which are in cultivation, viz., the above and *L. Plumieri*. The latter has erect leaves, the blade oval in shape and about 6 inches long, and the stalk three-sided, purplish at the base, and about 1 foot long. The flowers are produced on an erect scape, six or eight in a head or umbel, and they open generally two together; they are yellow, and about half the size of those here figured. *L. Humboldtii* is perennial, the other annual. The genus is related to *Alismas*, *Sagittarias*, and *Butomus*, and is found in streams and ditches all over South America. *L. Humboldtii* was introduced to Kew and the Liverpool Botanic Gardens in the same year, viz., 1833.

These plants require stove treatment, and should be potted in rich soil, submerging the pot in water kept at a temperature of 65° to 70° in summer and not lower than 55° in winter. If grown in tubs or small aquaria, fresh water should be added every day. W. W.

The Slough Nurseries.—At the present time there is in these nurseries such a feast of *Pelargoniums*, pot Roses, *Azaleas*, and *Carnations*, that all who are specially interested in these classes of flowers and that can conveniently have a look in will be well repaid for their pains. I had but an hour at my disposal, so that it was literally a run through, but for all that the pleasure derived was immense, for I have been feasting on the sight ever since. Lovers of show *Pelargoniums* that have bemoaned the fickle-mindedness of the horticultural public, because of the waning popularity of their favourites, by a visit now would have their enthusiasm raised to the highest point by seeing these at Slough, the fancy section in particular. All are models of skilful cultivation, but this section fairly captivated the writer—small pots, deep green vigorous foliage, and flowers of indescribable perfection. In an indirect manner I gathered that the cultivation of show *Pelargoniums* is not, as it once was, a financial success; all the more honour, therefore, is

* Drawn for THE GARDEN by H. G. Moon in the Royal Gardens, Kew, Sept. 2, 1886, and printed by G. Severeys.

due to the sons of the late Mr. Charles Turner, who for the reverence they bear for their late honoured father still continue the cultivation of his especial pets. The place once famous for elephantine specimens of Azaleas now knows them no more, but their place is better occupied by what are called half specimen plants, some 3 feet or a trifle more in height, to almost as much in width, and, like the Pelargoniums, flowered to perfection. Pot Roses I will not attempt to describe, for they will probably be otherwise reported on by the time this note appears in print, as on the day of my visit they were being prepared for a London show. Tree Carnations are grown by the thousand, and it is no exaggeration to say that many hundreds of plants are now in full flower, and scores are cut daily for bouquet-making. Auriculas have passed the meridian of beauty for this season, but there are still hundreds of plants in good flower, and these will shortly be succeeded by limitless numbers of Pinks, Picotees, and Clove Carnations, for which these nurseries have been famed for years, and by present appearance are likely to continue to be for many years to come.—W. W.

FRUIT GARDEN.

W. COLEMAN.

PACKING TENDER FRUIT.

PEACHES.—As much of the choice early fruit now grown is destined to travel to large towns, but principally to London, during the season, the art of perfect packing is quite as important as the art of growing, and yet many there are who lay the foundation of disappointment and annoyance before the finest examples of their skill leave their own premises. But few Peaches as yet have been gathered, but soon they will be plentiful, and as nine-tenths of these probably will have to travel hundreds of miles, not only by rail, but under the tender care of delivery companies, a few words upon this matter may be of use to some who have not had much practical experience. Peaches, it must be understood, are grown and managed for two distinct purposes, and although eventually all of them are supposed to reach the rich man's table, they require equally distinct modes of management. Growers for market gather as soon as the fruit has attained its full size and colour, and, although hard to the touch, in this condition it can be packed to travel safely, and arrives in the best possible condition for the fruiterer. It does not rest with me to prove whether these Peaches are better or worse than others that are allowed to become nearly ripe before they are gathered, but one thing is quite certain: they must be sent off in this state, otherwise they will have to be forced upon the market often in a damaged condition, when the consignor will be a considerable loser.

Private consumers, notably the owners, expect their fruit to arrive in perfect condition and fit for immediate consumption. Many of them have shrewd business managers about them who can greatly assist the grower, but the majority push the ripe and unripe to the front, hence the importance of making a careful selection, and packing in a way that the most tender examples shall arrive without spot or blemish.

PACKING MATERIALS.—Bran, wadding, and Moss are generally used for packing purposes. All cannot obtain Moss, but those who can will find this the safest, cheapest, and best, as it is soft, elastic, and never heats in the boxes. Bran, on the other hand, sinks in bulk when shaken on the journey. Moreover, it is liable to become heated, when a disagreeable flavour is imparted to the fruit. If this does not happen, unless very firmly pressed, the Peaches and packing separate, the latter settles to the

bottom of the box, and the contents arrive in a bruised, and possibly a worthless, condition. Extensive fruiterers, the best of all judges, are equally dead against cotton wool or wadding, as this also becomes moist, hard, and heated on long journeys during very hot weather. Assuming, then, that good ground Moss can be obtained, a plentiful supply should always be kept on hand, and the more it is beaten with sticks when not too dry, the better will it be adapted to the purpose. As regards boxes, they should be of uniform length and breadth, as several can then be corded together, the depth being regulated by the size of the fruit they are intended to carry. For my own use I have them made of stout half-inch deal, 14 inches in width, 24 inches in length, and 4½ inches deep, with lids in one piece, which should be lightly nailed down, but tightly corded, legibly labelled, to be met at the terminus. This is an important matter, as Covent Garden dealers will send a porter to any railway station in London, in preference to trusting this class of fruit to the delivery carts.

GATHERING AND PACKING.—Having quite recently described the best mode of detaching the fruit, I will in a few words explain my method of packing. Early morning, when the fruit is cool, is the best time to gather, the slightest pressure with the fingers being carefully avoided. Arrived at the packing room with each Peach resting on a square of silver paper, the boxes are prepared by lining the sides and ends with paper, allowing the half of each sheet to hang over the sides, for turning over when all is finished. A good layer of Moss is then placed in the bottom of the box; the Peaches, divided into firsts and seconds, are then neatly folded in the squares, the box is tilted on the right and packing is commenced at the left hand end. I then shake more Moss along the left hand end, place the first Peach in the corner, keep it in its place with the left hand, follow with more Moss and fruit until the first row of four is finished. Having introduced more Moss to form a division, the process is repeated until the box is full; each Peach is then resting in a soft nest of Moss an inch from the bottom and about the same distance apart. More soft elastic Moss is then gently, but firmly pressed in, firmness, it must be borne in mind, being the keystone of success; a good layer is then spread over the top, the half sheets are turned over, and the lid is nailed down. A little experience is needed in laying on the last layer of Moss, which should be somewhat higher than the sides of the box, as security depends upon every part being equally full, decidedly firm, and yet elastic. These remarks apply to fruit intended for market, but when large ripe Peaches have to be packed for immediate use they should be gathered a day or two before they are wanted. Great care must be observed in moving them, as the slightest pressure with the fingers is followed by a bruise, and an extra quantity of Moss must be placed beneath them. The folding of these and all tender fruit should be performed on a sheet of wadding, and every Peach should be packed apex upwards. Nectarines can be packed in the same way in boxes of the same size, as all can then be corded together for security.

FIGS.—Large ripe Figs require even more care than Peaches, and for this reason the boxes should be somewhat smaller. Good Moss or soft paper shavings answer best for these, but instead of enclosing them in tissue paper each fruit should be neatly folded in soft, dry Vine leaves and papered afterwards. This precaution is very important, as the Fig, owing to the tender nature of the skin and the abundant

moisture which it contains, soon absorbs the paper, when separation at the end of the journey is not only difficult, but detrimental to the appearance of the fruit. Packing in the boxes is precisely the same and equally simple, always provided the materials are soft, elastic, and perfectly free from moisture.

Pear Beurre Rance.—At the spring exhibition in connection with the Bath floral fête held on the 11th inst., prizes were offered for a dish of Pears, and Beurre Rance took all three prizes. Excellently well preserved and plump samples shown by Mr. J. Hooper Taylor were awarded the first prize. Mr. Taylor said he had kept the fruit in such good condition by hanging them up by their stems in a cool closet. The fruits shown were taken from a standard, and they were remarkably well flavoured; indeed, it is said the flavour is better from standards than from trees against a wall. Beurre Rance is a valuable dessert Pear for winter, and keeps in good condition until May. Two or three other varieties of Pears were shown—unnamed—but were decidedly poor in comparison with Beurre Rance.—R. D.

Fruit prospects.—The Apple trees generally are in a promising condition; old ones are in many cases literally covered with bloom; middle-aged and young trees are not so heavily laden as I have seen them. Apricots are wonderfully well set, especially the Musch-Musch variety. The Moor Park is also good. The following sorts of Plums are set well; Belgian Purple, Early Prolific, Washington, Dymond, Pond's Seedling, Purple and Yellow Magnum Bonum, Green Gage, Guthrie's Gage, and Orleans, but I do not think it safe to reckon upon a crop of Plums before the middle of June, for although I have noticed they have set well in previous years, the number of fruit has sadly diminished by midsummer day. Amongst Pears there is a fair crop set on young trees against south walls. Old trees have plenty of bloom. The sorts which have set the most fruit at present are Josephine de Malines, Brockworth Park, Williams' Bon Chrétien, Doyenné du Conice, Marie Louise, and Beurre Diel. Peaches have also set abundantly; Cherries are late in opening; Raspberries on our cold soil have come through the winter well; Black and Red Currants promise to be abundant; there is a fair show of Gooseberries, but not enough to make a heavy crop. Altogether the season's fruit crop at the middle of May promises well, and if we can get fair weather to tide us over the next three weeks, I do not think we shall have to complain of the want of fruit in the west of England this year.—J. C. C.

The bloom crop.—Whatever may be the favoured products of other countries, certainly few can compete with us in elements of beauty when all our varied fruit trees are in profuse bloom, and were no fruit crop to follow, the flowering period, with all its wealth of colour and beauty, would be some reward. We are now in the midst of the Plum, Cherry, and Pear bloom—all white, but still very charming. Of these, without doubt the chief elegance is found in the long-stemmed, graceful drooping Cherry bloom, which, almost always profuse, let the after crop be what it may, is this year singularly abundant, the long branches being hung densely with clusters of flowers. Plum bloom, if insignificant singly, is yet effective in the mass, and as some kinds of Plums are early and some late, the flowering period is rather prolonged. Pears have the advantage when in flower of a nice backing of foliage, which materially assists to display the snowy whiteness of the bloom. If last, certainly most beautiful, comes the Apple bloom, none the less charming that it gives more of colour after the abundant snowy hue of the trees preceding. In an unopened condition some of the Apple blooms show the richest colours, and may then challenge comparison with those found on other hardy trees. When it is all open and in that rich profusion which will be seen everywhere this season, a mass of delicately tinted beauty is found such as can hardly be excelled in any other country. Happily, there is abundant evidence that our sole reward for the cultivation of hardy fruit trees will this year be

found not in bloom alone, but also in an abundant crop of fruit of all kinds, assuming, of course, that all danger from late frosts is over.—A. D.

VINES AND GAS TAR.

If your correspondent "W. I. M." had read my notes carefully before criticising them he would not have needed to "hazard an opinion" as to my being in too great a hurry to tie the laterals down, for I think I made it plain that those only on the Vines which had been dressed gave me any trouble, and that I had others under my charge at the same time. To relieve his mind as to my knowledge of the great care required when tying down laterals, I may tell him that I was taught the mysteries (!) of that process nearly twenty years ago, and have had considerable experience in that way since.

"W. I. M." unconsciously strengthens my case when he draws attention to the fact that the laterals of Alicante and other strong-growing late kinds are especially liable to break off, for the Vines which were dressed were in my early and mid-season houses, and consisted principally of Hamburgs. My late house—a large one in which were several Alicante and other strong-growing varieties, never required or got any of the dressing, as it was nearly a new one and no bug had found its way there. These Vines never gave me any trouble, and it was this fact that led me to think, as I do, that the dressing was to blame.

We are told that nothing is needed but "tar and clayey water in equal proportions." Where is the lime? That used to be an important factor, and, as I think, a dangerous one. Still, it was recommended, and I was attacking the mixture as a whole, and have no experience with any modifications of it. Perhaps the tar will follow the lime after a while, and we shall have nothing left but the dirty and harmless clay.

On "W. I. M.'s" own showing, the mixture is, as I called it, a failure, for it will not do all that was claimed for it, as it does not kill all the bug. I do not think many gardeners will accept his statement, that of Gishurst and gas tar compounds, the latter is the "least liable" to injure the Vines.

I should not think of advising the use of paraffin as a "winter dressing" for Vines, but it is an excellent thing when used, as I advised, for bug in (apparently) isolated cases; for I believe there is generally a colony where one can only see a solitary specimen, and the paraffin spreads and destroys all the insects within reach. Of course, it, like gas tar, requires to be "intelligently" applied.

I have tried, and do not like, the plan of suspending the Vine rods "lower than usual," for though they may be brought up again, it is a tedious and difficult thing to do, especially where the wires are rather close together.

Your correspondent merely repeats me when he says that "any dressing powerful enough to kill them [bug] also damages the Vines;" but anyone in reading his criticism of my letter would be led to suppose that I had asserted the contrary. I was most careful to point this out, and to show that our winter dressings must be supplemented by strict attention in the growing season. In fact, a large portion of "W. I. M.'s" letter is a mere repetition of what I wrote.

A word as to red spider. I have managed many vineries, modern as well as ancient structures, but I never yet found one in which spider could not be kept down; and I think there is no better proof of radically bad management than to see Vines with their foliage badly disfigured by spider. No other insect, with the exception of thrips in enormous quantities, can sap the life of Vines so thoroughly as this pest does, and the sooner any structures in which spider cannot be kept down are razed to the ground the better—if the fault is in the structure.

Chelsea.

C. T.

SHORT NOTES.—FRUIT.

Ornamental Apples.—I should recommend "W. R. R." to plant the following sorts, viz., Beauty of Kent, Gravenstein, and Lane's Prince Albert. The two first named bear

very large clusters of white blossoms, with just a tinge of pink on the outside of the petals. We have some bush trees of these sorts that are now quite a sight. The last mentioned sort bears clusters of bright crimson coloured buds, which make the trees very conspicuous.—J. C. C.

Cucumber Purley Park Hero.—Perfect fruits of this are about 15 inches in length, spineless, of a deep bright olive-green colour, and perfectly symmetrical throughout, with scarcely any handle. It represents a very fine type, and it will be found of great value both for table and exhibition purposes. A brace of fruit staged at the recent Bath show appeared to be as perfect as Cucumbers could well be.—R. D.

Vines bleeding.—Would some experienced Grape grower tell me the cause of my Vines being so wet every morning, causing them to continue dropping until the sun dries them, through which it has brought mildew? I ceased syringing a week ago. The buds are just bursting. I give plenty of air during fine weather and shut up in the afternoon about 3.30. What would remedy this evil?

P'ZZLED.

*** The cause of your Vines bleeding is no doubt brought on by late pruning, and results from the pores not having time to heal over and close up before the sap begins to move. Many plans have been tried to stop this bleeding, such as applying paint or knotting, sealing-wax, &c., but in most instances they have failed, and the result therefore must be left to Nature to cure. If mildew has attacked the Vines, heat the hot-water pipes, but not a flue, and paint them with the sulphur mixed with water, or dust the sulphur all over the Vines, and in the course of a few days wash it off with rain water. ED.

Summer-pruning Currants.—Those who have not yet given the plan of summer pruning or pinching out the growing tops from Currant bushes a trial should do so without delay, as it is while in the full flush of growth that the operation must be done to be successful, for if not done until the wood gets hard and requires cutting it had better be left altogether, as by that time the under leaves will have been so blanched by the dense top growth that they will fall off when fully exposed. We go over our bushes directly the leading shoots are about 6 inches long and pinch the tops out; the lower leaves then get strong and remain on the bushes all the season, and the buds at their base get very much stronger than if all the strength were allowed to rush up into the wood, which at the winter pruning will be cut off. There is really very little winter pruning to do if summer pruning or pinching is attended to, as the young wood that is left gets so completely covered with flower-buds that one is loth to cut any of it away. Red and White Currants are apparently the most benefited by close pruning, but black varieties are also much improved by stopping the leading shoots that are as high as they are intended to be left for fruiting, the young growths from the base for supplying new fruit-bearing shoots being left intact. It is simply a question of concentrating the forces of the bush on fruit or useless wood production.—J. G., *Hants.*

SEASONABLE WORK AMONG FRUITS.

ALTHOUGH sharp frosts have prevailed, the weather having been unusually dry, fruit blossoms so far are quite safe, and crops of all kinds up to the present date are extremely promising.

PEACHES have set a profusion of fruit; the trees are remarkably clean, and being well furnished with leaves cautious cultivators may now look forward to full crops which will require much thinning. Where fishing-nets have been used for protecting the flowers, some, if not all of them, should be allowed to remain, as we never know what a night may bring forth, especially since our springs have been swallowed up by winter. My best wall, coped with broad boards and covered with three thicknesses of netting, has thrown off 12°, 8°, and 11° of frost, and not a single flower has, I believe, been injured. These nets are removed, one at a time, at short intervals, but the copings remain till June, when they also are taken away to let in the light and air and to give the trees the full benefit of rain and dew. The most important work here is dis-budding and washing with plenty of pure water, as many a newly-started colony of insects can be

broken up by this agency alone; and all must admit that a stitch in time often averts the use or abuse of dangerous insecticides. Owing to the lateness of the season I have only just commenced dis-budding, and this operation is carried on in a very careful way. First of all, we take the foreright shoots and thin out the clusters; then, following the Seymour system, nearly all the breaks from the lower sides of the shoots are taken; and, finally, those on the upper sides are thinned or pinched to two or three leaves in preference to laying the young fruit bare. By adopting this plan the most delicate trees do not feel the check; neither do sharply root-pruned trees come to a dead stand after they have exhausted the stored-up sap. It is yet early to think of much thinning, but doubles and triples may be reduced to one, naturally the best fruit and inferior fruits may be rubbed off after the trees have thrown off, or by washing have been divested of, the remains of the flowers. Many people living in cold districts commence pegging or tying in the shoots at a very early stage of their growth, but I prefer allowing them to make some progress before anything of the kind is attempted, as many a tender shoot is injured by the slightest pressure. Moreover, a half-abandoned growth, until we have true summer weather, is favourable to the free flow of sap, and certainly to the rapid development of the fruit.

PEARS AND CHERRIES, Morellos excepted, are now in full bloom, and a grand sight they are. Clean, healthy, and bold, I never recollect seeing these walls more promising. A profuse bloom is not, however, always the best earnest of heavy crops of fruit, as it is by no means unusual for such floriferous trees, especially in dry seasons, to exhaust themselves. Early, very early in the season I drew attention to the light rainfall, and suggested timely watering. The dry weather continues, and those who have looked well to the roots, not only with water, but with light warmth-admitting mulching, will most likely reap their reward. Very early wall-trained Plums and Pears are now forward enough for pinching, but beyond checking gross foreright shoots, this excellent protection to the fruit should be allowed to remain until all danger of frosts has passed away. This delay must not, however, be carried too far, as timely pinching is the best and surest mode of checking luxuriant growth and converting wood into blossom buds. Greengages and Coe's Golden Drop with us, thanks to the bullfinches, are thin, and this reminds me that a keen observer once said that these birds gave preference to the buds of choice varieties, whilst common sorts in close proximity remained untouched. How far this may be correct, I am unprepared to say, but certain it is that the best sorts of Plums and Pears here have suffered most. A continuance of this dry weather may bring a plague of aphid almost before the fruit is set; the best preventive is winter syringing at short intervals with soapsuds, and again as soon as the young fruit commences swelling, but black fly is not so easily kept in check. Tobacco water applied in time is perhaps the safest and best remedy, but more than one dressing or dipping must be applied, otherwise it will be a source of annoyance throughout the season. Tobacco powder is sometimes used; indeed, the names of insecticides are legion, but the most common fault is delay in their application. Yet another set of marauders about this time the fruit grower must hold himself prepared to do battle with, and as these, the Apricot and Plum grub, do not succumb to insecticides, hand-picking and crushing with the finger and thumb must be closely followed up. Their work of destruction does not last long, but unless timely and determined steps are taken the ruin of the finest crops is certain. Last, but not least, we have the Gooseberry caterpillar, a most voracious destroyer. Many remedies, some of them poisonous, consequently dangerous, have been recommended, but, applied in time, there is nothing better than light dustings of freshly slaked, but cool lime. If with some force this is cast upon the ground and into the centres of the trees, the fine particles will rise through the foliage, and if they do not instantly destroy they will dislodge, when the extra quantity of lime on the surface will prevent them from rising again. All these remedies are excellent in their

way, but the use of them might often be prevented by the timely and bountiful application of pure water, which not only cleanses and invigorates the foliage, but breaks up the homes of insects before they have time to gain a firm foothold.

Turning to the open quarters, there exists but little doubt that fruit trees of all kinds, especially those which have been root-pruned or transplanted, would be greatly improved by a warm and steady rainfall. If this were to continue for twenty-four hours and mild nights followed, trees now in arrear would very soon redeem the time they have lost; if, on the other hand, rain does not come, watering and mulching must not be neglected. One good soaking is more effectual than repeated dribbles, and water from open ponds or tanks is better than the most copious supplies from underground mains.

RASPBERRIES AND STRAWBERRIES, two moisture-loving subjects, must not be overlooked, as dryness at the roots is one of the most common causes of failure. Like all other fruits, these are unusually backward, but the latter, especially young plantations, are now throwing up very strong trusses of flowers. These naturally give fruit of the finest quality, but plantations of the preceding year produce the greatest quantity. If extra fine fruit from either is wanted, timely thinning and supporting, to keep the berries up to the sun and safe from slugs, must be resorted to. The best spring mulch is fresh stable litter, always provided it is not too heavily charged with ammonia, and this should be placed amongst the plants before the young leaves and trusses become too prominent. The manurial properties it contains then get washed down to the roots by rain or artificial watering, and becoming bleached and sweet it forms a cheap and suitable surface for the fruit to rest upon. Old plantations which lost many of their leaves are still backward, and although the trusses no doubt will be plentiful, it is not unlikely they will be weak. To these we give liberal dressings of old Vine border soil, and dust the surface with soot before it is raked down into the stools in March. On cold borders this dressing answers better than manure, as we find now surface roots strike into it at once, and whilst making the stools distasteful to slugs, the soot acts as a powerful stimulant.

NEW PLANTATIONS may still be made either from the reserve beds of last year's runners or from forced plants. Many people use the latter, take one or at most two crops, and then trench them. I do not, however, care for them, for, independently of the fact that they are more or less weakened by forcing and the check which follows, they invariably carry with them spider or mildew, or perhaps both, and unless they are extremely well planted, mulched, and watered they compare unfavourably with maidens of the same age. The usual practice of raising generation after generation from old plants, if not in the original beds, certainly on the same kind of soil, must tend to degeneration, but when those plants are enervated by forcing, by parasites, and insects the constitution must suffer. This in a great measure may be averted by propagating every year from young plants which have been put out in new soil and divested of their maiden trusses before the flowers open. By adopting this plan none but fertile plants are used as stock parents; all their strength is thrown into the runners, which, as a natural consequence, are much earlier than others from fruit-bearing plants. To those who would carry Strawberry culture to its very highest point let me commend change or exchange of runners, as Potato growers exchange their seed, and I venture to say complaints of wearing out will be few and far between.

FIGS.—Where Figs have been hard hit and time has been allowed for doubtful shoots to declare themselves, a careful examination of the trees should now be made, and if it is found any of the points have been killed they should be shortened back to good buds to ensure young growths for next year's fruiting. Those left must then be nailed in close to the wall, and the better to hasten the swelling of the young fruit, light mulching, followed by copious

watering with warm water, must be brought to bear upon the roots. Wall Figs do not require an extensive root run, but the wall paths, high and dry, should be full of firm, well-ripened fibres, the drainage should be ample, and their food should be plentiful enough to ensure perfect maturation of the fruit without producing a gross habit of growth. In extra snug quarters, where the let-alone system results in good annual crops of fruit, the removal of all damaged shoots should not be neglected, as masses of half dead wood impede the circulation of fresh, warm air, and throw out weak, useless spray, whilst cutting back to a good bud will result in a shoot, from which fruit in due time may reasonably be expected. When this has been done a few barrowloads of half rotten manure may be cast over the roots, and an occasional watering that will reach the lowest depths will set them right for the summer.

THE ORCHARD.—Newly-planted trees will still require attention, not only with water, but with an extra supply of loose, non-conducting mulching. Necessarily this need not be very rich, as properly prepared stations should foster good growth when the roots have taken a firm hold of the soil, but the season having been so dry the wood buds cannot get beyond a tuft of small leaves, which will harden into fruit buds where this timely assistance is withheld from them. When standard trees are planted on deeply trenched stations and the supporting stakes are driven down into the firm subsoil, the soil sometimes settles and drags or strangles the roots. In this way many good trees are ruined not for the season, but for all time, and thorough planting being an expensive operation, all these defects, trilling in themselves, should receive speedy remedy. Of the three evils—wind-waving, chafing against the stakes or strangling—the first is the least, but all can be avoided by the use of two stakes instead of one—an inexpensive item in any district. Hay bands, as a rule, are twisted round the stakes before the trees are tied, but, unless they are cradled for security from young stock, rough Moss, which is less palatable, answers better.

Newly grafted trees must also be examined. The mechanical part of this work being satisfactory, success in a great measure depends upon the perfect exclusion of air, especially from large branches carrying two or three grafts until such time as the union is complete. The best of grafting clay in the best of seasons sometimes cracks, and as this generally happens soon after the work is finished, now is the time to replaster with a rather thin composition of stiff clay and cow manure. Another important matter will shortly claim attention, and that is the American blight or woolly aphid, not only on old-established trees, but on others previously clean that were grafted a year or two ago. This troublesome pest not unfrequently is carried into healthy orchards with grafts from a distance, and although it does not make much progress the first season, the second favours its rapid development. Careful grafters cleanse their scions before they insert them; those who neglect this precaution should lose no time in dressing every tree with an insecticide that will destroy it. Half a pint of gas-tar or a like quantity of paraffin added to a gallon of the thin stopping just recommended and well worked in with an old brush above and below the division will be found a safe and never-failing remedy, or Gishurst compound, pure and simple, will answer equally well. The fact that American blight produces canker has been disputed, but I have ample proof that the wounds which it produces are exactly like canker and certainly not less injurious. Orchard prospects in this locality are very promising, and so far the trees are clean and free from blight. Twenty-four hours' rain from a warm quarter would now be a godsend not only on dry soils, but upon every orchard throughout this part of the country. W. C.

Tomatoes well grown.—Mr. Gilbert sends us very good specimens of his Tomatoes grown in small pots, both foliage and fruit. Better could not be. We hope he will not forget the old red, which, treated as well as the new var. etc., would be a better and handsomer fruit. So many are grow-

ing Tomatoes now that we should be pleased to have some details of his way, size of pots, &c.

KITCHEN GARDEN.

W. WILDSMITH.

WEEDING, HOEING, AND MULCHING.

THESE are three essentials of good cultivation, and, as regards the first, I consider the most common-sense way of looking at the matter is that, since it is impossible to have a good vegetable crop and a weed crop off the same ground at one and the same time, therefore the weeds should be destroyed as soon as they are discernible, or, at any rate, before they are of sufficient size to at all rob the soil of any of the properties that ought to be solely appropriated by the vegetable crops. To this end it is necessary that one's mind be thoroughly imbued with the importance of the subject; then will be found ways and means of doing the work, however short-handed we may be—I mean in reason, and where hands are allowed in something like reasonable proportion to land under cultivation. If these conditions cannot be afforded, then the next most profitable plan of culture would be to reduce the amount of ground, and do that well, and grow on it but one crop at a time, and by thus giving no quarter to weeds, the probabilities are in favour of at least as heavy a crop of vegetables from reduced ground as from a much larger plot which—of necessity from lack of labour—must be weed-infested. But the remark will no doubt be made, any and every crop is liable to get overrun with weeds. Yes; but the fault does not lie with the weeds, because they can at all times be destroyed; and the second phase of our subject, namely—

HOEING, is the best way of effecting their riddance, and, better still, of preventing their appearance, and, still better, of assisting growth, which the loosening of the surface soil does by rendering the ground the more easily susceptible of atmospheric influences. Nor are these the only merits we must attribute to hoeing, for the practice is indispensable to the obtaining of the highest results in the cultivation of all crops that have to be grown so close together, that the third phase of our subject, namely—

MULCHING, cannot be carried out. Of course, in respect of all crops to which mulching can conveniently be applied, hoeing is unnecessary and mulching is a necessity, if the highest order of cultivation is the aim; no matter what the character of the soils may be, the practice is alike desirable and beneficial for the heaviest as for the lightest, for if applied to the former it prevents the soil cracking or fissuring open to the injury of the roots, and for the latter it renders artificial watering unnecessary in the driest seasons. But I am forgetting, by pre-supposing that the best material for mulching—long stable manure—is plentiful, which is not the case in every place (it is not here), but when it is, we use it in preference to any other, and after it is done fall back on the short Grass from lawn mowings, and when thus reluctantly compelled to use such material, a sprinkling of soot or some kind of artificial manure is first applied, and the Grass over this. For Peas, Beans, Celery, Globe Artichokes, and large breadths of Cauliflower, we have come to regard the application of mulching of the utmost importance.

Broccoli growing.—Your correspondent "J. S. W." tells your readers that it is not "men" that I want to grow Broccoli, since I can find any number of cottagers that grow vegetables better

than one-half the gardeners of the country, which is perfectly correct, and I have not one word to withdraw from the sentence, because I can prove the assertion. I asked "J. S. W." a simple question—Would he call a Broccoli hardy when only thirty-eight plants die out of 1215? "J. S. W." answers the question, I should presume, by saying that it is not one or two frosts which kill a Broccoli, but a spell of continued frosts. Surely in all conscience sake we have had that continuation this winter, and still the Broccoli lives! "J. S. W." says probably they have been covered up a portion of the time, but I say not one iota of protection has been near them. The description of Chou de Burghley taken from Backhouse's catalogue is an accurate one. Although I have never mentioned the fact that a Broccoli head is enclosed in the Cabbage, I nevertheless know it to be a fact that when Chou de Burghley is running to seed in the spring it shows a small Broccoli, which personally I have never mentioned, for the simple reason I did not think it worth while. The description given is not of my writing, but a testimonial, of which I have received a great number. —R. GILBERT.

Hardy Broccoli.—Mr. Gilbert, in THE GARDEN (p. 375), says that I am mistaken in supposing that crowbar-planting of Broccoli is not generally practised by market growers, and cites an instance in support of his argument that happened thirty years ago in Kent. Well, I have seen a good deal of market culture of both vegetables and fruit in Kent, but never had the good fortune to see the crowbar in use, so that it has made slow progress. It matters little by what implement they are planted provided they are put out on firm ground in an open, sunny spot and not drawn up in the seed beds, or by overhanging trees or pent-up, walled-in gardens, for if they are grown under these conditions an average winter will destroy them. I do not think that the gardens at Burghley are a fair sample of the kind of kitchen gardens that are attached to the country residences of English gentlemen, and therefore the fact of Mr. Gilbert being able to grow short-legged Broccoli does not prove that the average run of gardeners are incapable of growing good Broccoli. Why should a man who is a gardener be less able to grow Broccoli or any other vegetable than a cottager? Mr. Gilbert was too hard on gardeners, for they can only be expected to do the best with the means at their disposal, and I have seen hundreds of gardens so overshadowed by trees and enclosed by walls, that it would puzzle the most accomplished grower to keep his crops from becoming drawn up and leggy. Gardeners have enough to contend with without their own brethren making matters worse.—J. GROOM, Gosport.

Early Potatoes.—Whilst early Potatoes are being lifted in Cornwall from under glass, and their earlier breadths outdoors are so forward as to suffer severely from late frosts, here, in the neighbourhood of London, except in extra warm gardens, early Potatoes have made no sign, and with the nights still so cold and mornings so frosty, it is just as well they are beneath the soil. But it is evident that this lateness in growth means late cropping, and thus the prospects of market growers in obtaining a profitable return are very poor indeed. Early Potatoes will come in this year only after the market has been glutted with the produce of warmer climes, and the edge taken off from the public appetite for new Potatoes. As a result, whilst we shall doubtless see a big crop, having regard to the great breadths which have been planted, we shall also see very low starting prices. If that prospect would induce growers to allow their crops to remain a few weeks longer in the soil to further increase and mature, growers and consumers would gain. We have had, and shall have, for the next two months a sterile time in market gardens, and something is wanted to turn into money. Thus necessity drives many growers to rush up their Potatoes long before they are fit for lifting, if, indeed, only a bushel per rod of decent ware can be obtained. As the selling price will probably not exceed 2s. 6d. or 3s. per bushel, early Potatoes hold out no great prospect of proving remunerative. By its early and considerable cropping

qualities, Beauty of Hebron has almost monopolised market ground. It is an excellent Potato for eating when grown on Middlesex soil, but, like all immature Potatoes, has little flavour when so early lifted.—A. D.

KITCHEN GARDEN NOTES.

PEAS.—Our first batch are now in flower; they were sown in pots and planted out. The first sowing made in the open border early in February will not be in flower for ten days or a fortnight, the little extra labour that sowing in pots entailed will therefore be rewarded by our being able to pick a fortnight or so earlier than otherwise would have been the case. The first to open flower was Veitch's Extra Early, Sutton's Ringleader only a day or two later, and Laxton's William the First a week after Extra Early, but the high quality of William the First more than compensates for the few days longer it takes to come to maturity. Another sowing of late kinds is now to be made—sorts, British Queen, Ne Plus Ultra, and Latest of All. Successional sowings have been staked, and mulching put on a yard in width and about 4 inches thick; this keeps them in an equable growing condition; consequently we hardly know, from practical experience of having to battle with mildew, how difficult it is to exterminate that parasite when once it has got a firm hold. The cause of it is invariably the result of a check to growth, and the most general cause of such check is drought. Moral—dig or trench deeply, manure freely, sow in trenches, and mulch as soon as staked.

RUNNER AND DWARF FRENCH BEANS.—The first sowing of dwarfs has come up well, and is already thinned out to about 9 inches apart, and soil has been drawn well up to them as protection in case of frost, and having a good supply of Yew spray, this will be laid over them should it be deemed necessary. A small sowing of Canadian Wonder will now be made each week up to the end of June. The second principal sowing of runners we have just made on ground recently occupied with Brussels Sprouts, so that deep cultivation was a necessity, for there is no crop—not even Peas—that so effectually impoverishes the ground as does this variety of the Cabbage tribe; but it is only just to add that the produce afforded is adequate to repay the maximum amount of impoverishment.

LETTUCE AND ENDIVE.—A small sowing of Lettuce is now made about every ten days, and sowing is done where the plants are to mature, as transplanting does not pay during the summer months, for plants so treated quickly run to seed. A moist, half-shaded position, if the soil be fertile, produces the finest, most crisp, and juicy Lettuces during the summer months, but ground being limited we have more frequently to make it a makeshift crop, and grow it on the Celery ridges between the rows of Peas, amongst fruit trees, and, in fact, on any bit of spare ground. White Cos varieties are most favoured, for under all conditions of cultivation they are more generally tender and juicy than any of the Cabbage varieties. We have now sown Endive, Green Curled and the Broad-leaved Batavian on a west border, and the plants are intended to mature there, and as soon as large enough to be thinned out we shall make a successional sowing in the same way as Lettuce, the two being quite on a par in respect of resenting transplanting in the summer-time. The sudden burst of sunny weather rendered watering of lately transplanted Lettuce of the utmost importance.

PARSNIPS.—These are of sufficient size to be thinned out, but the ground has got so hard that we shall have to wait for a shower before it can be done. We thin out to from 10 inches to 12 inches apart, and the rows are 18 inches asunder, which in good ground is not a bit too much. As soon as thinning out has been done the ground between the rows will be hoed as deep as non-injury to the roots will admit of; another hoeing immediately prior to the tops of one row touching that of its neighbour will be all the cultivation needed for the remainder of the season.

TOMATOES.—The plants being strong, in 5-inch pots, and well hardened, have this day (11th inst.) been planted out, a few of them on suitable places against the walls of houses and pits, but the bulk occupy a large space of the best west border we have, and which is well screened from the north-easterly winds that oftentimes do serious damage to some of our early vegetable crops, and, profiting by such mishaps, we never fail to note the positions in the garden on which the wind has least effect. The plants are 36 inches by 46 inches apart, and to each a stout stake is placed to which the main stem is secured as growth progresses. The ground is moderately rich, and each plant is set, as it were, in a shallow basin, so that in case of excessive fertility, when additional stimulus may be requisite, manure water will be the more readily applied, and meantime the depression in ground will ensure that, whatever rainfall there may be, a full share of it will descend directly to the roots. The varieties planted out are Earliest of All, Reading Perfection, Hackwood Park Prolific, and Trentham Fillbasket.

RIDGE CUCUMBERS.—These we have now planted on ridges, the foundation of which consists of about one-third long litter and the remainder short Grass, the mowings from the lawn. The soil is principally the siftings from the potting shed, a few barrow-loads of leaf soil and droppings being mixed with it. The bottom-heat now registers 86°, and is steadily declining, else we should not have ventured to plant. The bulk of litter and Grass is of sufficient depth to warrant the hope that the heat will not decline to a less degree than 70° (and probably not lower than that the whole of the season) before the plants have gained sufficient strength and root-run, after which they will do right well if the temperature does fall a little lower than that. The plants are at present protected with handlights, but by the end of the month, when we expect to be quite safe from frost, these will be taken away, for the plants resent coddling. "Slow and sure"—that is, slow, vigorous growth, then sure and free fruiting—is a certainty, of course all other items of culture being duly attended to. The more important of these are the keeping of the plants well supplied with water, the foliage clean and free from insects, and the growths so regulated by frequent thinning and pegging that it may never be necessary to cut away a large quantity of leaves and growths at one time, and thus cause a check to growth that frequently ends in gumming and canker. W. W.

HOEING.

WHEN walking through a market garden a few days ago my attention was arrested by a man hoeing. He knew his business, and he did it thoroughly and conscientiously. There was no mere skimming of the surface with him. He bent his back, keeping his hoe handle almost horizontal; and, striking the hoe down into the soil sharply, he drew it towards him to the length of 18 inches or so, loosening the soil thoroughly to the depth of two or more inches. This I thought was doing his work in a proper manner, and the crop among which he was hoeing could scarcely fail to be benefited by the operation. I remember Mr. George Paul once telling me that he encouraged his labourers in his nursery at Cheshunt to hoe deeply, by paying them a kind of premium, and he found deep hoeing of great advantage during a dry summer, ground with a loosened surface not giving out so quickly as that with a hard and unloosened surface.

The hoe serves other purposes than merely that of chopping up weeds. This is important, because the soil produces a crop of weeds naturally, and that in spite of the old tradition that it does so because a curse rests upon it. The earth is a bounteous mother to man, producing a very large part of his most wholesome food, and is therefore very much more of a blessing to him than a curse. Tillage is of the first importance; the better the soil is tilled the more generous are the crops, and one of the most important details of tillage is hoeing.

But, in addition to chopping down weeds, the hoe loosens the surface of the soil, when by reason of heavy rains it has run together on the surface

and become baked by the sun. As Glennly puts it, the pores of the soil become closed up, and the hoe remedies this. And this observant gardener remarks, in using the hoe, "work straight before you, slicing the earth, as it were, by drawing the instrument to you with a pressure towards the ground, thereby cutting off everything that comes in its way; and if you wish to stir the earth a little deeper, turn the corner of the implement a little, when the same pressure makes it penetrate deeper. You put the hoe to the ground a foot or so before your advancing foot, and draw it close to you. This is the operation, too, for thinning crops of Turnips, Carrots, Parsnips, Spinach, and any other produce that is sown too thick. You cut up all but sufficient to grow, and those you leave at proper

operator, and therefore he does not tread upon the fresh stirred soil. But there are several degrees of hoeing. The principal one is to keep the surface soil loosened, and market gardeners especially, who may be said to rush crops through the ground in their eagerness to secure and market them, are fully alive to its value. Good culture is one of the main springs of success. R. D.

FERNS.

W. H. GOWER.

ODONTOLOMA.

This genus comprises about half-a-dozen distinct species, which are by some authors placed

Odontoloma repens.

distances." As a matter of course, the hoe has to be applied with care in the case of young crops not long through the soil. As yet the young plants have but a slight hold upon the soil, and care must be taken not to disturb them, or they will be in danger of being burnt up by the sun. A careful hoer works by common-sense rules, and avoids mistakes of this kind. Among young fruit trees, Roses, &c., the soil may be stirred deeply without fear of harm, because the crop is well established.

There is one objection to the ordinary garden hoe: he who uses it has to tread upon the ground he has just stirred. It is different with the Dutch hoe, because it is used by being pushed from the

with Lindsæas, and by others with the Davallias; from the former, however, *Odontoloma* is distinguished by its sori being punctiform, whilst in *Lindsæa* it is linear and continuous, and they differ from *Davallias* in having the pinne developed on one side of the mid-rib only. Other known species which, although handsome and desirable ornaments for our plant houses, have not yet been introduced to cultivation are *O. pulchella*, *Parkeri*, *hymenophylloides*, *tenuifolia*, &c.

O. REPENS, the subject of our illustration, known also as *Davallia repens* and *D. hemip-*

tera, is an epiphytal plant, having a slender, creeping sarmentum, or root-stock, producing linear pinnate fronds, a foot or more in length, the pinne being about half-an-inch long, developed on one side of the mid-rib only, dentate on the edge, and bright lively green in colour. This plant is seen to the greatest advantage when grown in a suspended basket. It enjoys strong heat and a moist atmosphere, and should be placed in soil composed of fibrous peat and *Sphagnum* Moss, through which should be disposed some rather large pieces of charcoal. In potting or handling this plant, care should be taken that the points of the rhizomes, which are very brittle, are not broken. It may be readily increased by dividing the root-stock with a sharp knife in early spring, just before the young fronds push up. It comes from various islands in the Indian Seas.

Todea pellucida.—If I was asked to name a Fern which would give the least trouble to its possessor, and yet be always in a satisfactory condition in a sitting-room, it would be *Todea pellucida*. It will thrive either in a warm or cold room with subdued sunlight or in constant shade, and requires little or no water after it is once properly planted, always looks green and refreshing, and is a source of constant interest to a plant lover. I have a plant in my sitting-room which now nearly fills the glass shade which covers it. Seventeen months ago it was a small plant with some five or six fronds, and was then planted in the pan which now holds it and covered with the glass shade. It has never had a drop of water since, in any form either to root or frond, and the shade has never been taken off, and yet it is in the most flourishing condition. The glass or terra-cotta pan in which the *Todea* is to be planted should be prepared as follows: Put an inch thick of *Sphagnum* (or Moss of any kind if *Sphagnum* is not to hand) all round the sides and bottom of the pan; half fill it with clean broken potsherds or bits of broken brick; on this put a thin layer of *Sphagnum* or Moss; then fill up the pan with a mixture of pounded potsherds (or bricks will do) and fibry peat broken up small, leaving it a little high in the middle; in this insert the plant of *Todea* and finish with a thin surfacing of *Sphagnum*; give a good watering with a fine Rose sufficient to saturate the whole mass; then put on the glass shade at once. Put the Fern case in the window or on the table of the room where you wish it to be, and it will prove a source of pleasure for many months, and require no further care till the glass shade becomes full of fronds, when it will be necessary to take off the shade and cut away some of the oldest fronds, or to begin again with another small plant.—ROBT. LLOYD, *Brookwood*.

A PROTEST.

TO THE EDITOR OF THE GARDEN.

SIR,—Some nurserymen, supposed to be innocent persons and good citizens, sometimes grievously afflict their customers in certain little ways.

1. They send me plants with names horribly written, often in pencil. A label sent out by any methodical nurseryman should be such as would last a season through. It is not always convenient for me to label my plants permanently as they come, and I frequently find plants so labelled that the words cannot be read a few weeks after the plants arrive.

2. They send plants "to compensate for carriage," not knowing whether I want the said plants or not. In this way I get plants which I do not know, and therefore do not care to sacrifice space for, also some that I dislike!

3. They often take it on themselves to add to my order, and to send things not ordered in place of those that are desired.

4. Instead of giving the name of the plant they give the number kept, unfortunately for

me. for reference in their books. This is an impertinence which the bestowal of a catalogue occasionally containing the corresponding names does not atone for. Our sweet and reasonable system of naming plants is so loved by us all, that we resent being kept off by numbers! Foreigners are very fond of the number trick.

5. Some few soil shrubs packed without any moist material about the roots, so that in dry weather they are injured or killed. It is easy to so pack any plant that it may travel for days without letting the moisture escape from the roots.

6. Cases of officiousness, well meant, but misapplied. I order *grandiflora*, and the nurseryman writes, "You ordered *grandiflora*; we have substituted *grandiflora superba magnifica splendens*, a much finer variety, which we feel sure will give satisfaction." Now, *grandiflora* is the right size, and of a beautiful soft rose colour, which perfectly satisfies my eye, while the so-called improvement is a coarse-looking flower of a virulent magenta colour which I abhor. E. X.

TREES AND SHRUBS.

SHRUBS FOR ORNAMENTAL PLANTING.

THE STAFF AND SPINDLE TREE FAMILIES are known in our shrubberies by two genera of plants, both of which have representative species from abroad as well as native. Most of these, among other good qualities, have showy fruit in autumn.

CELASTRUS SCANDENS (Climbing Waxwork or Bitter-sweet) is well known as a beautiful native vine, clean in appearance, rapid in growth, brilliant in autumn with the orange and scarlet of its fruit, and cheerful with glossy foliage all summer. Considering the rather limited number of our hardy ligneous climbers, it is strange that this attractive vine is not more freely used. *Celastrus articulatus* and *punctatus* are species from Japan that grow still faster, have broader leaves and fruit much earlier than our own. The fruit, however, comes in smaller clusters and is less showy. All of them do best in strong soil, but it should be remembered that some of the vines do not have female flowers, and therefore bear no fruit. Planters should be sure to procure female plants.

EUONYMUS ATROPURPUREUS (the Burning Bush) is a shrub some 6 feet to 8 feet high, found along streams from New York to the Carolinas, with dull chocolate flowers in late June, and bright red fruit which hangs on well into winter. Trained to a single stem it assumes a neat, round-headed form which is most attractive.

EUONYMUS AMERICANUS (Strawberry Bush) is a low shrub with inconspicuous flowers, but brilliant scarlet fruit. This, too, is known as the Burning Bush further south, and grows some 6 feet high. With us it is low, half trailing, and admirable for covering rocks or clambering over banks. The variety *obovatus*, from rocky woods in Pennsylvania, is a slender, trailing Evergreen with long, narrow leaves and scarlet berries.

E. ELATUS (the Winged Spindle Tree) comes from Japan and forms a dense head, rarely more than 3 feet high. Its flowers, too, are dark and lustreless, but the early fruit is of bright red, and the foliage turns to orange and scarlet in autumn. There seems to be two varieties of this species, one of which has much more marked "wings" than the other.

E. VERRUCOSUS is so called from the warty appearance of its branches—singular dark-brown excrescences on the green bark. It comes from Austria and Hungary, and grows 8 feet or 9 feet high.

E. NANUS is a beautiful low Evergreen, resembling somewhat in appearance *Daphne Cneorum*. The purple flower clusters are rather pretty and abundant, and the pod which follows is of a bright rose colour and opens to show a deep orange berry. It grows

rapidly, will do well in a somewhat shady and dry position, and makes a most effective addition to the list of trailing or creeping plants for banks and rocks.

E. LATIFOLIUS, from Germany and France, is a small tree in habit, and about the best of the whole family. The leaves are broad and glossy, the flowers greenish white, the fruit large and brilliant and hanging on long stems. This species should not be crowded among other shrubs, but allowed to develop its beauty as a single lawn tree.

E. RADICANS is a climbing species from Japan that clings to wood or stone by rootlets like those of the climbing *Hydrangea*, and in its home it is found with this plant and the *Ampelopsis* covering the walls of temples. The variegated form, with white markings in the leaves, forms a neat edging for walks when clipped. It does not do well under the drip of trees.

E. SHEOLDIANUS is also from Japan, a glossy Evergreen with greenish white flowers, and fruit which does not reach maturity here. It does well on the south side of rocks in well-drained soil, as a half trailing plant. Mr. Falconer writes that with him it becomes a dense hemispherical sub-evergreen bush and a very handsome garden plant.

E. JAPONICUS in many varieties are evergreen shrubs, some with leaves variegated with white and yellow markings. Here they are not quite hardy, but south of Washington they flourish in the open ground. A species from Japan called *yessoensis* promises well, but has not yet fruited.

E. EUROPEUS (European Spindle Tree) is a large shrub, reaching in some varieties a height of 20 feet, and has rose-coloured and orange fruit. It is more liable to insect attacks here than other species. The wood has been used for spindles and knitting needles from the earliest ages. It is also used for piano keys, cups, pipe bowls, and as charcoal for artists. It has many varieties, one with white fruit, another with purple, another with green, one with much broader leaves than the species, and one (*E. c. var. nana*) that grows scarcely more than 2 feet high in the form of a miniature Lombardy Poplar. J. DAWSON, in *Arnold Arboretum*.

Exochorda grandiflora.—There appears to be numerous forms of this very excellent plant in cultivation in gardens, all of which vary more or less in the size of the flowers. The majority of the specimens we have seen belong to the small-flowered form, the large one being apparently more rare. It is a most useful plant for a wall, and, if kept trimmed properly, makes a fine covering, being at the present time a sheet of pure ivory-white and green. Although a good wall plant, it makes a handsome isolated specimen, the pretty twigs giving it a grace of its own, not surpassed by any other flowering shrub we are acquainted with.—L.

Fabiana imbricata.—This pretty flowering shrub is hardy in favoured spots in the south of England, and will survive most winters against a wall around London, but, generally speaking, is seen at its best when grown under greenhouse treatment, and so treated it is now in full flower, and at the same time very attractive. Though it belongs to the Order Solanaceae, the whole character of the plant is widely dissimilar from its common allies, for it bears a great general resemblance to a Heath, not only in habit and foliage, but also in the flowers, which are tube shaped and pure white in colour. It remains in flower a considerable time, and is altogether a very pretty greenhouse shrub of easy culture.—J.

The double-blossomed Cherry.—Cherries everywhere appear to be flowering with great profusion this season, and this floriferousness characterises the double Cherry also. Here, at Ealing, in two of our forecourt gardens, there are very fine specimens, and the oldest of the two, a tree perhaps of forty years' growth, is a marvellous example of floriferousness. The blossoms are in crowded wreaths, so closely are they set on the branches that they realise the poet's description of being "heaped up in happy plenteousness." The specimen looks as the naked trees did nearly five months

ago, when the light, feathery snow gathered on their branches and encased them in a garb of perfect whiteness. The blossoms of the double Cherry are snow-white. The plants should always have full space to develop their branches when planted; no neighbouring trees should be near them to interfere with their natural growth, or hide them from view.—R. D.

The flowering Currant as a hedge plant.—I lately saw a hedge composed of this plant, and a splendid sight it afforded, covered as it was with its drooping racemes of flowers, which had a very rich effect, and rendered it at once a striking object as well as a capital fence. The plants had been pruned closely in when first planted, and as growth had been freely made the leading branches had been allowed to make each year just sufficient young wood to produce a crop of blossoms. The form of the hedge was perpendicular with a flat top. The upright growth at the sides admitted of the bunches of blossoms hanging in a natural manner. One annual clipping, and that during the winter months, is all that was found necessary to keep the hedge within prescribed limits.—E. M.

Viburnum plicatum.—This Japanese species of Guelder Rose is well fitted for growing in pots and flowering under glass, for with ordinary care and attention it will in this way bloom well every year, and the large clusters of pure white flowers form not only a prominent feature, but will remain in beauty a considerable time. Besides being very ornamental when grown in this way, it also forms a very handsome plant for training on low walls, as in such a situation it will flower well, but as an open bush it seldom blooms in a satisfactory manner. One point worthy of notice with regard to this *Viburnum* is that it will bloom in a smaller state than the common Guelder Rose, which last, however, is from an ornamental point of view second to none. *V. plicatum* is by no means the easiest of the genus to increase; indeed, cuttings do not strike readily, so that the better way to propagate it is by means of layers. T.

Magnolia Campbelli.—It is much to be regretted that there should exist two serious impediments to the successful cultivation of the above-named handsomest of all flowering trees known to temperate climates, as all must admit who have seen the splendid portrait of it given by Sir Joseph Hooker in his fine work on the trees and plants of the Himalayan region. These impediments are, first, the extreme brittleness of its timber, which renders its main stem (even when of so considerable a size as between 40 feet and 50 feet in height) liable to be snapped in two by any violent gale of wind, even when in by no means a specially exposed situation and when surrounded by high trees. This catastrophe happened this spring at Laklands to Mr. Crawford's second largest specimen, 36 feet of the main stem, carrying numerous flower-buds, being thus unfortunately broken off, to its owner's great grief. The second is that, from its time of flowering taking place at least six weeks too early for our uncertain climate and before there is a vestige of foliage on the tree, the beautiful flowers, being unprotected by any calyx, are liable to get caught and have their lovely roseate petals blackened by such late frosts or a continuance of harsh easterly winds as we have had this spring. I have recently been informed by Mr. Crawford that, though his finest specimen has over 100 buds this spring, he fears that none of them will open for the above-stated reasons.—W. E. GUMBLETON.

SHORT NOTES.—TREES AND SHRUBS.

Weeping Hemlock Spruce.—In a letter, Mr. S. B. Parsons, Flushing, Long Island, speaks very highly of his Weeping Hemlock Spruce. This tree appears to be very little known in our country. He says his specimen is now a picture.

Prunus Pisardi.—Although this *Prunus* is thoroughly distinct all the summer, it is never more so than in the spring just as it is unfolding its leaves, which are of a soft purple colour. This shrub is very conspicuous when associated with green-leaved deciduous trees. Towards the autumn the red coloring of the under-side of the leaves appears to assume a stronger tone. It is certainly a desirable tree for the shrubbery, and is said to bear purple-coloured flowers.—J. C. C.

Deutzia crenata flore-pleno.—This double form of the favourite *Deutzia* is a valuable open-air shrub. It is of graceful habit, assumes a large size, and in May or early in June it becomes a complete mass of snowy flowers. Before these wither they become of a purple hue. The plant ought to be included in all collections of early summer-flowering shrubs. Our largest specimens are about 7 feet in height, as much through, and they have been very pleasing objects when in bloom ever since they were 18 inches high.—CAMBRAN.

Spirea Thunbergii.—Of all the small shrubs I have grown, I know of none more beautiful in winter than this *Spirea*. Its real beauty is not fully developed, however, till the plant is at least three years old. The spray is small and delicate, and prettily recurved. The leaves are about 1 inch long, and very narrow and Willow-like. The plant is quite dwarf, and rather solidly furnished, except it be thinned out. To my mind, it is a most beautiful object when covered with its tiny white flowers very early in the spring.—M.

Pyrus sinensis.—Just now, when so many kinds of *Pyrus* are conspicuous by reason of their showy blossoms, this species furnishes an additional attraction in the shape of the rich bronzy red tint of the expanding foliage, which feature causes it to stand out distinct from all its associates. It is a somewhat sturdy growing, medium-sized tree, reaching when full grown a height of 20 feet or thereabouts. Though it is one of the earliest of all the *Pyruses* to burst its leaf buds, the foliage is in the autumn retained very late. The flowers are, like those of most of its class, pure white, and stand out very conspicuous against the bronzed foliage. *Pyrus salicifolia* affords a direct contrast to the last named, for the young leaves are of a hoary whiteness, which causes it to be very noticeable wherever planted.—T.

Berberis Aquifolium as a specimen.—It may not be generally known what a capital plant grows as a specimen upon the Grass the common Mahonia makes. Seldom do the commoner kinds of shrubs, both evergreen and deciduous, have a chance to show their natural beauties under the most favourable conditions, being generally planted in some out-of-the-way corners. I lately saw growing upon a small lawn in front of an amateur's residence a bush of this *Berberis* fully 5 feet high and about 7 feet through. It had not been pruned in closely to form a dense bush, but the branches had grown in an upright manner, each one at a distance from its neighbour sufficient to allow of the full development of the foliage, and for the display of bloom. The lightness of the whole bush, contrasted with the rich green foliage and golden-coloured blossoms, rendered it at once a conspicuous and noteworthy object.—E. M.

Rubus deliciosus. Mr. William Thompson, of Ipswich, was, I believe, the first to advertise seed of this pretty shrub. It was from his seed that I raised several plants, retaining two for my own garden and giving away the rest. The method of increasing the plant by cuttings of the current year, as recommended by your correspondent "T." in THE GARDEN (p. 104), will, I doubt not, answer the purpose, if the method adopted for Currants and Gooseberries has not hitherto proved successful. The seeds of this shrub, like those of many other perennials, are hard-coated, and have to lie a long time in the ground before they will germinate. I sowed my seeds in a pot in the usual way, and having filled up the little space at top with silver sand, I buried it in the ground in a sheltered spot. At the end of twelve months I raised it to the surface and removed most of the sand, and about the middle of May the plants appeared. Having a small quantity of the seed left, I sowed it and treated it in the same way, but it was two years before the seed germinated, and this I have no doubt was owing to the seed having been kept a longer time. Some old seed of the *Mimulus cupreus* that I had had in the house for several years was sown in a pan by the side of some new seed of the same species. The plants from the latter soon appeared, but there were no signs of vegetation in the vacant space till about six weeks afterwards, when the little plants were seen in profusion, the seed having been sown rather thickly. Hard-coated seeds are better sown as soon as possible after being gathered. Treated in this way, I have found the seed of the Dog Rose to germinate freely after being in the ground sixteen months.

They make good stocks for budding when well grown and of sufficient strength.—B. S.

ORCHIDS.

W. H. GOWER.

ORCHID SHOWS.

DURING the past few years it has become the custom with several of the large London nurserymen to hold exhibitions of these plants in their own establishments, to which their patrons and the public are cordially invited, and there can be no doubt but this practice has considerably tended to popularise Orchids, and to increase a taste for them. In this way the display of bloom far exceeds that possible to produce at any ordinary exhibition; the plants can be seen in a more natural manner, in many instances in the houses, and under the conditions in which they are grown; thus exhibited there is no necessity to resort to the practice of transferring numerous small flowering plants into one pot in order to make up a huge mass of sufficient size to enable the exhibitor to carry off the prizes competed for, which not only led to erroneous ideas, but too frequently resulted in heavy losses through the death of plants subjected to this treatment; again, as a far greater number of species and varieties can be seen and studied in this way than could possibly be brought together in any flower show, the benefits to the lovers of Orchids is proportionately greater; moreover as these exhibitions are continued over several weeks, they are convenient to those who may be unable to gratify their tastes on any one particular day on which a flower show may be held. At the present time two of these Orchid exhibitions are now on view, viz., at Mr. B. S. Williams, Victoria and Paradise Nurseries, Upper Holloway, and at Mr. Wm. Bull's, King's Road, Chelsea; in each of these establishments several hundreds of varieties of Orchids are now to be seen, whilst many hundreds of plants go to make up the sum total of the display.

In Mr. Williams' nursery, a large Palm house, 100 feet in length, is devoted to the exhibition of Orchids alone, these plants being backed by the beautiful greenery of large Palms and Cycadaceous plants, whilst smaller Palms and graceful Ferns are judiciously inter-mixed, and which combine to make up a perfectly enchanting and fairy-like effect. Notable in this display are large examples of *Vandas*, for which this nursery has become famous, such forms as Dr. Paterson's variety of *V. tricolor* and *V. suavis* *Hrubayana* being specially prominent; *Laelia purpurata*, with its large and showy white and purplish violet flowers being very conspicuous. These are associated with numerous exquisite varieties of *Cattleya Mossiae*, *C. Mendeli*, *C. Aelandiae*, and the yellow and fragrant Tulip-like blooms of *C. citrina*, which cannot by any means be induced to grow upwards, but which invariably creeps downwards, its large flowers hanging in the air like huge golden pendants. To these must be added the rosy mauve *C. Skinneri* and the magenta-flowered *C. Lawrenceana*. *Odontoglossums* contribute largely to the display, the lovely and popular Princess of Wales's plant (*O. Alexandrie*) being represented by hundreds of spikes, and in almost endless variety. Other members of this genus of Mountain Orchids now blooming are the chaste *O. Pescatorei*, various forms of *O. Andersoni*, *O. gloriosum*, the bold and showy *O. triumphans*, *O. citrosimum*, *O. odoratum*, *O. sceptrum*, and the elegant *O. cirrhosum*. Yellow flowers to vary the scene are supplied by grand examples of *Oncidium Marshallianum*, the rare *O. lamelligerum*, *O. concolor*, and *O. sarcodes*, *Dendrobium densiflorum* and *suavisimum*, *Anguloa Clowesi*, *Ada aurantiaca*, *Epidendrum vitellinum majus*, and *Laelia cinnabarina*. Lady's Slipper Orchids are also well represented, some of the chief forms being *C. ciliolare*, the rare and beautiful *C. tessellatum porphyreum*, which is a hybrid raised between *C. concolor* and *C. barbatum*, the flowers being suffused with a rich port-wine colour; *C. conchiferum*, which may be described as a very much improved *C. Pearcei*; *C. levigatum* (*philippinense*), *C. selligerum majus*, *C.*

granule, *C. Bogalli*, and the curious *Tropidium Lindenii*, which is a near ally of *Cypripedium caudatum*, but it does not produce a slipper-like pouch, but instead a long-tailed segment resembling the petals. *Masdevallias* also, with their brilliant flowers, contrast and blend beautifully in this arrangement, the finest of them undoubtedly being *C. Veitchi grandiflora*, rich in colour, and with blooms measuring 7 inches in diameter; various forms of *M. Harryana*, such as *rosea*, *cerulescens*, *blacina*, and *atro-sanguinea*, *M. ignea* and *M. Chimera* being most conspicuous. Moth Orchids (*Phalenopsis*) are represented by *P. Schilleriana*, *Ludlemanniana*, *rosea*, the spotted-flowered *P. Stuarti*, and the chaste rose-coloured *P. Sanderiana*. *Calanthes* contribute their quota, not only the evergreen section, such as *C. Dominii* and *C. venetifolia*, but one of the vestita section called *Sanderi*, with pink sepals and petals and rich crimson lip. This form is said to always bloom about this season, and is therefore a valuable addition to this genus. Space forbids a more lengthy detail of this fine show. Passing from the Orchids, one finds a most brilliant and varied display of *Anthuriums*, such kinds as *A. Scherzerianum*, *A. Wardianum*, and *A. Andreanum*, besides which there is a house devoted to *Azaleas* in bloom, and another to Cape and New Holland plants, in which *Heaths*, *Acacias*, *Pimeleas*, *Bononias*, *Tetrathecas*, &c., are very conspicuous.

Mr. Wm. Bull's Orchids are also magnificent. They are artistically arranged with small and elegant Palms and Ferns, which form the best of all backgrounds to flowers, and hide the pots in which the Orchids are grown. As at Mr. Williams', *Laelia purpurata*, *Odontoglossums*, *Oncidiums*, *Cypripediums*, *Cattleyas*, and *Dendrobiums*, in almost countless numbers, form the groundwork of the display, several hundred different forms and many hundreds of plants being required to fill the large house devoted to the show; whilst in the smaller houses quite an army of plants are in reserve pushing up flower-spikes to replace those which have preceded them. Besides most of the species and varieties previously noted, there are here some grand specimens and excellent varieties of *Cymbidium Lowianum* and *C. burneum*, both species preferring somewhat cool treatment; a very handsome form of *Cattleya Schlegelera* called *albescens*, numerous fine examples of *Miltonia vexillarium*, *Roezli*, and *Roezli album*; and the smaller, but not less beautiful *M. Phalaenopsis*, all these being perhaps better known as *Odontoglossums*. Amongst less known Orchids notable were *Scuticaria Dodgsoni*, a species which resembles *Steelei* in growth, but appears to bloom more freely than that species; the flowers are thick and fleshy in texture, light brown, blotched, and transversely banded with light yellow; lip white, streaked with rose. It is a plant which will not grow erect, and enjoys strong heat and an abundance of moisture. *Brassia Keiliana* is a very interesting member of a genus which appears to be regaining favour. Its flowers, which are produced on a long raceme, are yellowish brown, with a white lip, the sepals and petals being lengthened into narrow long tails. *Celogyne pandurata*, with its green and black flowers, and the Butterfly *Oncidiums*, *O. Papilio* and *O. Krameri*, are numerous. *Oncidium nigratum* is a rare and pretty species from Guiana, and produces large much-branched spikes bearing a profusion of flowers, the sepals and petals of which are pure white, barred with deep chocolate, the triangular lip being blotched in front with the same colour, with a yellow crest. This species thrives best in an intermediate house. *Oncidium macranthum* is well represented, this variety being highly coloured, and the flowers rounder and fuller than any we have previously noticed. Many forms of *Lycaste Skinneri* are also conspicuous. These have been grown and kept in a low temperature with the view of their lasting for the present purpose. The rare *L. gigantea*, although it can hardly be called a showy Orchid, is wonderfully distinct, having bronzy green sepals and petals, and a velvety maroon-fringed lip. Amongst distinctive-leaved Orchids are various forms of *Vanda tricolor* and *suavis*; the summer-flowering variety of *Angraecum sesquipedale*, *Aerides suavisimum*, *odoratum* and *crispum*; *Saccolabium guttatum*, and *Phalaenopsis grandiflora* lend their

charms. We strongly advise our readers to see these exhibitions for themselves, for no description, however lengthy, could do justice to their excellence. G.

DENDROBIUM WARDIANUM.

THIS magnificent species, originally imported from Assam, was for a time scarce, but has since been found plentifully in a new locality; consequently it can now be procured at a very reasonable rate. It is of pendulous growth, and generally grown in baskets and pans, but the longest growth I have ever had was 5 feet 3½ inches grown in a pot. The plant from which the spike figured in the annexed engraving was taken was grown in a pot along with other varieties in the Dendrobium house. The plants are potted chiefly in peat, with a little Sphagnum Moss and a good addition of charcoal, the plants well elevated above the rims of the pots and kept at all times near the glass. During

air or at the root, as it is apt to start into growth from the crown. When this takes place the lower blooming buds do not open, although the growths have been well ripened.

I do not practise the so-called pruning system, but the growths are frequently cut off to the crown when in bloom for house decoration, for which use as well as for exhibition purposes they are well adapted. This magnificent genus of Orchids (*Dendrobium*) produces in some of the species flowers which are very large and delicate in colour and delightfully fragrant, whilst many of them produce flowers in great abundance. Many of them retain their leaves all the year round, whilst others are deciduous. Some of the kinds are compact in growth, while others are straggling; again, others are most graceful when cultivated in baskets and suspended from the roof. The majority of the species are found in various parts of India and the Indian Islands, growing on the branches of

Dendrobium Wardianum. Engraved for THE GARDEN from a spike of flowers sent by Mr. A. Evans.

the growing season the syringe is used freely amongst them, as well as a plentiful supply of water at the roots, until the growths are completed. The plants are then removed to a Muscat vinery to ripen, which place suits them well. Water must be reduced gradually, but not to such an extent as to make the pseudobulbs shrivel. Young plants should at all times be grown in small baskets or pans. This variety will flower quite as freely as the old *Dendrobium nobile*, producing from twenty to thirty flowers on a growth in pairs and threes, the best variety measuring from 3 inches to 4 inches in diameter. They bloom about May, and continue a considerable time in perfection. I have had them keep fresh in the flowering compartment five weeks. Where a number of plants of this variety are grown they should be introduced into heat in batches, so that there may be a continuous supply of bloom kept up, according to the demand, from Christmas till June. One thing must be closely observed with this variety when at rest—not to keep it at all moist in the

trees such as hang over streams of water, whilst others are found in Australia. A. E.

Lytell Hill, Haslemere.

SHORT NOTES.—ORCHIDS.

Orchid sale.—Mr. G. F. Wilson, of Weybridge, writes that his hardy and half hardy plants now take up all his available time; therefore his collection of Orchids will be sold at Stevens on Thursday, June 2.

Oncidium aureum.—This very pretty species is now blooming in the collection at Kew. It produces a long branching spike bearing many flowers, which are in the sepals and petals of a dull reddish crimson, whilst the large flat lip is golden-yellow. It appears to thrive in the intermediate house. As we have not observed this species in any other collection, it is probably a rare plant.—G.

Odontoglossum Masereeli.—This form has originated from amongst an importation of plants from Ocaña, and gives one the impression of being a hybrid between *O. luteo-purpureum* and *O. pratinens*. The flowers are about the size of *O. luteo-purpureum*, the sepals and petals being large and broad, golden-yellow in colour, the latter bearing several obscure transverse bars and spots, lip white, profusely crested. The raceme of flowers was sent to Kensington. It came from M. Masereel, of Ghent. It appears to much resemble *O. Vultstekeanum* of Reichenbach.—G.

ORCHIDS AT CHELSEA.

THE display of *Laelia purpurata* and *Cattleyas* at Messrs. Veitch's nursery is just now very grand, between 500 and 600 of these beautiful flowers being all open at one time. The gorgeous beauty of the sight, however, cannot be imagined, neither can it be adequately described, as it must be seen to be appreciated. The house in which these plants are grown is about 140 feet long with a centre stage, and from end to end on both sides there is a perfect blaze of beauty, for associated with the *Laelias* are countless numbers of *Cattleya* blooms, notable amongst which are fine varieties of such kinds as *C. Mendeli*, *Warneri*, *Mossiae*, *intermedia*, *Skinneri*, *Lawrenceana*, *Laelia elegans*, &c. Rich and rare though the display is at the present time, the innumerable spikes which are just pushing out of their sheaths bid fair to maintain a succession quite equal if not to eclipse the present display a few weeks later on. The conditions under which these plants have been grown to produce this wonderful crop of flowers appear to be good exposure to sun and light, a somewhat cool atmosphere with free admission of air, with just sufficient moisture to prevent either roots or flowers suffering from aridity. In the same house are some notable examples of the Cow's-horn Orchid from Honduras (*Schomburgkia tibicinis*), and what a beautiful plant it is when seen in flower as it is here; its large and numerous blooms are more richly coloured than usual, owing no doubt to having been well exposed to the sun. This fact should be borne in mind by cultivators of this plant, as but very few are successful in its treatment.

CYPRIPEDIUMS have a house, which contains numerous magnificent specimens, devoted to themselves. They are kept somewhat warm and moist, but even here there is nothing like saturation, and air is freely admitted. The most conspicuous of the kinds in flower are the rare *C. Morganie*, one of the hybrids raised in this establishment between *C. superbiens* and *C. Stonei*; the leaves in shape resemble the latter, but they are somewhat obscurely tessellated in the way of the former; the scape is three-flowered, dorsal sepal white suffused with red, the veins being of a darker hue; petals broad and long, white tinged with pale yellow, profusely spotted and blotched with brownish purple; the lip large, yellowish white tinged with purple. *C. grande* is another of the Messrs. Veitch's hybrids raised from *C. Roezli*, crossed with *C. caudatum*. It is a much stronger grower than either of its parents; the flowers are very large, the petals much longer than those of *C. Roezli*, and the lip is much extended. *C. grande* bears as many as four flowers upon a spike, all open at the same time. *C. Druryi* has not yet been seen to great advantage, but, judging from a variety now flowering in this collection, its rich yellow flowers will render it a great favourite. *C. ciliolare* is a bold and handsome plant introduced from the Malayan Islands, and appears to combine the beauties of *C. argus* and *C. superbiens*, whilst in *C. vernixium* the Messrs. Veitch have obtained a hybrid which blends the charms of *C. argus* and *C. villosum*. Some varieties of this, however, appear to be finer than others, although all originated from the same cross. Other kinds flowering here are *C. Swainianum*, *superciliare*, *Hookeri*, *caudatum*, *Roezli*, *Lawrenceanum*, *conchiferum*, *barbatum*, *Warneri*, and various others.

In the houses devoted to those plants requiring the greatest heat are members of the showy *Dendrobium thyrsoiflorum*, with quantities of its pendent trusses of snowy white and orange-yellow flowers. *Dendrobium Jamesianum*, bearing some thirty flowers, is truly grand, its large white flowers, slightly stained in the lip with pale yellow, being very conspicuous. It appears to thrive here remarkably well treated as a basket plant, exposed to full light, and all but full sun. Other *Dendrobiums* now flowering are *D. Bensoniae*, *Parishi*, *tortile*, *albo-sanguineum*, *Dalhousianum*, *crystallinum*, and a charming form of *D. Farneri* named *album*, with large flowers, which are in the sepals and petals pure white, with orange-coloured lip. Associated with these *Dendrobies* is the spring-flowering form

of *Angraecum sesquipedale*, its large waxy white, long-spurred flowers being very conspicuous contrasted with numerous spikes of *Aerides Veitchii*, bearing much-branched racemes of delicate, soft, rosy pink, shell-like flowers, and with the dense racemes of the Fox-brush *A. Fieldingi*. *Vandas* are flowering in quantity, and their grateful aromatic fragrance pervades the whole house. In the coolest house a large and graceful display may be seen, numerous large, branching panicles of *O. cirrhosum* being associated with similar ones of *O. Edwardi*, the former with pendent twisted sepals and petals, pure white, blotched with chocolate, and the latter deep purplish violet. Intermixed with them are innumerable spikes of *O. crispum* and *Pescatorei*. These, with immense spikes of *Oncidium Marshallianum*, bearing many of its large, rich, golden yellow flowers, blotched with chestnut-brown, form the groundwork of the display, from amongst which peep out the bold flowers of *Odontoglossum luteo-purpureum*, *O. vexillarium*, *maculatum*, *gloriosum*, *triumphans*, *Cervantesi*, and its variety *decorum*, *cordatum*, *Roezli*, *citrosinum*, and the clear yellow *Oncidium concolor* and *O. macranthum*. All these plants are grown in a cool temperature, the condition of the plants and the vigour of their flower-spikes bearing ample testimony as to how well the treatment suits them.

W. H. G.

CHRYSANTHEMUMS.

E. MOLYNEUX.

THE time is now fast approaching when the plants that were struck from cuttings in December and early in January will require their final shift into the pots in which they are to flower. Provision should accordingly be made in advance for their safety when they are stood out of doors, such as protecting them from late frosts, which often come upon us unawares. Although *Chrysanthemums* are hardy plants when grown under natural conditions, they are rendered much more tender when the cuttings have been taken from plants which perhaps stood thickly together, as the young shoots under such treatment are sure to be more tender than otherwise, and these sometimes are pushed forward in a little heat and made to grow as succulent as possible, that they may assume the proportions of a walking-stick in the stems. No wonder, then, that they are unable to withstand a sharp, late spring frost with impunity. The placing, then, direct from houses or frames of the plants to an open position without any means of affording the slightest protection, is a step in the wrong direction. Plants that have been hardened in growth by the admission of a free circulation of air by day and night are in a much better condition to go directly out of doors than when otherwise treated. At this season of the year east winds, which oftentimes prevail, should be specially guarded against, as much havoc is caused by the wind bruising the tender, succulent leaves, if not breaking them off entirely. The tissues of the leaves are often so much injured as to deprive the plant of its natural support to a great extent; at the foot of a south wall the plants may be stood, if such a position is available; failing this, and the plants have of necessity to stand in the open, they may be fenced around with hurdles thatched with straw, or canvas or mats may quickly be placed over the top, which will then be a sure protection from frost at night, and the hurdles by day will shield them from cutting winds; nothing is better than a bed of coal ashes whereon to stand the plants. With hot sun and drying winds and small pots full of roots, water will be required twice, and sometimes oftener during the day. Close attention should be paid to them in this matter. At this season of the year many plants will

assume a sickly hue, notably such kinds as *M. Arlene*, *Criterion*, *Boule d'Or*, *Val d'Audorre*, *Golden Dragon*, *Album plenum*, and *Japonaise*. This is owing to a weakness in their constitution at this stage of their growth. As a rule this sickly colour in time wears off, and the plants regain their natural green shade; an excess of water at the roots or cold draughts of air in their younger stages all tend to aggravate such a complaint. Where plants are so affected it is wise in removing them out of doors to stand them by themselves in a snug corner, and by judicious attention to watering they may quickly recover as the season advances.

Chrysanthemum notes.—One result of the exhibitions of these most useful of autumn-blooming plants that are now held in almost every part of the country may be seen in a general improvement in their cultivation. In this I do not include the training of those monstrous flat specimens 6 feet or 8 feet in diameter, which are as objectionable as anything in the way of plant culture could be. But leaving these out of the question, more thought and attention are now given to secure a much higher standard of excellence than used to be aimed at, even where the plants are only required for greenhouse or conservatory decoration. The bad treatment that these and some others of the most useful things will submit to, and yet be able to live and flower in some fashion, is, no doubt, to some extent the reason of their being indifferently managed. Simple as the cultivation of *Chrysanthemums* is, if the plants are expected to produce the maximum quantity of well developed flowers, and to possess the amount of good healthy foliage at the time of blooming, that adds so much to their appearance, there must be no neglect from the time the cuttings are struck up to the time the plants come into flower. Unless the leaves from the base upwards are produced under conditions that are favourable to their attaining the requisite substance and solidity to admit of their keeping fresh and healthy to the time of blooming, they die off and leave the stems bare and unsightly, with a corresponding reduction in the strength and ability in the plants to mature their flowers. Plants that after being struck were moved into 4-inch or 5-inch pots must not be kept in these too long, as if their removal to the pots in which they are to flower is put off until they suffer for want of enough sustenance to keep them in free growth, they receive a check which no subsequent attention will make up for. Cool treatment during all the stages of growth from the striking of the cuttings onwards, plenty of light at all times, rich soil, no stint of moisture, liberal feeding with manure water when the time for giving it has arrived, and perfect freedom from insects are all requisite to grow *Chrysanthemums* well. In regard to stopping the shoots, it is necessary to be guided by the form the plants are required to be grown to; if the ordinary bush shape where each plant should consist of six or eight branches, and which for general use is best, one stopping will be enough, providing the young plants are strong, as when in this condition they will push more shoots than if weak.—T. B.

Gardeners' Orphan Fund.—The one thing that has been proposed is within the power of everyone, and yet the gardeners themselves are responding so slowly, and seem so bent on seeing what others do before they act themselves, that one would imagine they had no will of their own. If each one did what I first suggested and gave their 5s. yearly, it would enable us to start at once; but if they feel willing to give more (then give it, and not wait for others), the result would be that those who now wait would let us know what we could do, and would soon know how their money would be used and what a vast amount of help it would give. I certainly am sorry that my brethren seem so chary when the call of real charity comes in, especially as some of our best men give, and are willing to give, their time and assistance at their own expense for this good cause. I can only ask all my fraternity to canvas for the fund at once, and with a will,

and I am sure they will surprise themselves and others with the good results.—CHAS. PENNY *The Gardens, Sandringham.*

SOCIETIES AND EXHIBITIONS.

ROYAL BOTANIC SOCIETY'S EXHIBITION.

MAY 18.

THE first of the summer shows of this society was in every respect a very fine one, although, as at the last year's May exhibition, the weather was not propitious. The show was made up much in the usual manner, which must necessarily be the case, when little or no alteration is made in the schedule of classes from year to year. The only departure from the stereotyped display is brought about by the miscellaneous groups staged by the nurserymen, for which there is neither class nor prize offered, and over which there is therefore no restriction. Upon the present occasion these groups were both large and varied, staged with considerable artistic skill, and contributed in no small degree to the general effect of the exhibition.

STOVE AND GREENHOUSE PLANTS IN FLOWER. In the nurserymen's classes for twelve and six, Mr. Cypher, of Cheltenham, was first with the following plants, all of which were models of good culture and most profusely bloomed: *Erica depressa*, *Aphelaxis macrantha purpurea*, *Azalea Criterion*, *Pimelea spectabilis*, *Anthurium Scherzerianum*, *Franciscea eximia*, *Acrophyllum venosum*, *Dracophyllum gracile*, *Darwinia tulipifera*, *Erica ventricosa magnifica*, *Pimelea Hendersoni*, &c. Mr. James, of Norwood, came next with many of the same plants, and, in addition, fine examples of *Boronia pinnata*, *Darwinia Hookeri*, *Bougainvillea glabra*, &c. In the amateurs' classes Mr. W. Chapman, The Gardens, Hawkesyard Park, Rugeley, was to the fore with grand examples of *Tetradlea hirsuta*, *Statice profusa*, *Darwinia tulipifera*, *Acrophyllum venosum*, *Ixora coccinea*, various *Ericas*, *Azaleas*, &c. Other exhibitors in these classes (two and three) were Mr. Wheeler, Mr. Butler, gardener to Mr. Gibbs, St. Dunstan's, Regent's Park, and Mr. Offer, gardener to Mr. Warren, Handcross Park, Crawley; these collections contained similar, but smaller plants of the above-named species. Amongst distinct kinds staged by Mr. Offer were *Clerodendron Balfourii*, *Statice Gilberti*, *Boronia elatior*, and *Pimelea decussata*. It is much to be regretted that a greater variety of stove and greenhouse flowering plants are not brought forth. Why are the beautiful bright-flowered *Chorozemas*, the *Eriosteomons*, *Hoveas*, *Dillwynias*, and many other plants that bloom at this season not considered worthy of a place in such gatherings?

ORCHIDS had four classes provided for them, and they were well represented. In the amateurs' class for twelve, Mr. Hill, gardener to Mr. Little, The Barons, Twickenham, was placed first, with clean and healthy finely bloomed plants, well arranged; they were *Cypripedium caudatum roseum*, *Cattleya Mossiae* (twenty flowers), *Odontoglossum Pescatorei* (sixteen spikes), *Cattleya Skinneri*, *Dendrobium thyrsoiflorum*, *Oncidium Marshallianum*, *Odontoglossum Hystrix*, *Lycaste Skinneri* (twenty flowers), *Cattleya Mendeli*, two varieties, and *Dendrobium Dalhousianum*, &c. Closely following him came Mr. J. Douglas, Great Gearies, Ilford, with well-grown and flowered *Odontoglossum Roezli* and its variety *album*, *Cypripedium villosum*, with about fifty flowers, slightly past their best, *Masdevallia Lindenii*, fresh and good with nearly a hundred flowers, and a very good variety of *M. Veitchii* bearing ten blooms, a grand *Oncidium ampliatum majus*, *Cattleya Mossiae*, *Dendrobium Wardianum*, and *Cymbidium Lowianum*, which appears to make very long spikes, and bears a quantity of flowers, but it is a most wretched variety. In the class for nurserymen Mr. Cypher staged *Cattleya Mossiae* and *C. Skinneri*, *Laelia purpurata*, a magnificent specimen of *Dendrobium thyrsoiflorum*—the number of its flower-spikes it was quite impossible to count; also *D. chrysotoxum*, *Odontoglossum vexillarium* and *citrosinum*, *Calanthe veratrifolia*, *Oncidium ampliatum*, and *Vanda suavis*. Mr.

James, Castle Nursery, Norwood, followed with bright examples of *Oncidium concolor* and *Marshallianum*, *Masdevallia Harryana* and *Lindenii*, *Odontoglossum Alexandriae*, *Pescatorei*, and *vexillarium*, *Cattleya Mendeli* and *Mossiae*, the Fox-brush *Aerides*, and the fine old *Dendrobium fimbriatum oculatum*. This collection was followed by Messrs. Jackson and Sons, Kingston, with nice plants of *Cypripedium Lawrenceanum*, *barbatum*, *grandiflorum*, and *villosum*, *Aerides Piellingeri*, various *Masdevallias*, *Cattleyas*, and *Odontoglossums*. In the amateurs' class for twelve single specimen Orchids, Mr. Douglas was the only exhibitor. His best plants were *Cypripedium Dominicanum* and *Harrisianum*, *Oncidium Marshallianum*, *macranthum*, *ampliatum majus*, *Cattleya Mossiae* and *Mendeli*, and the form of *Cymbidium Lowianum* previously referred to. In the corresponding class for nurserymen, Mr. James, of Norwood, and Mr. Cypher, of Cheltenham, were awarded equal firsts. The former staged *Saccolabium retusum*, *Oncidium Marshallianum*, *Epidendrum vitellinum majus*, *Vanda suavis* and *tricolor*, *Laelia purpurata*, various *Cattleyas*, *Masdevallias*, and *Odontoglossum vexillarium*. Mr. Cypher's best plants were a very fine *Laelia purpurata*, *Odontoglossum vexillarium*, and a very highly coloured *O. citrosimum roseum*, various *Cypripediums* and *Dendrobiums*.

ROSES were both numerous and good. In the nurserymen's class for nine distinct varieties, Messrs. Jackson and Sons, Woking, wrested the place of honour from Messrs. Paul and Son. Messrs. Jackman's plants were superb, grand in foliage and flower; the best were *Victor Verdier*, *Celine Forestier*, *La France*, *Cheshunt Hybrid*, *Star of Waltham*, *Charles Lefebvre*, *Camille Bernardin*, and *Fisher Holmes*. Messrs. Paul and Sons' plants were fine, but wanted a day or two more to be at their best; the varieties were similar to Messrs. Jackman's, but *Charles Lawson*, *centifolia rosea*, *Magna Charta*, and *Juno* were very fine. Mr. Rumsey also staged nine excellent plants in this class. Class ten, six Roses in pots (amateurs), Mr. T. Lockie, gardener to G. Fitzgerald, was first with fine *La France*, *Etienne Levet*, *Mdme. Jamain*, *Mdme. Thérèse Levet*, *Marquise de Castellane*, and *Jean Liabaud*. Another pretty six were contributed by Mr. Peiry, gardener to Mr. W. G. Rawlett, The Woodlands, Cheshunt. The class for twenty Roses in 10-inch pots, not less than ten varieties, produced three competitors, viz., Messrs. Turner and Sons, Slough, Messrs. Paul and Son, Cheshunt, and Messrs. Jackman and Sons, Woking. Amongst the superb small specimens of Messrs. Turner, the following were most notable: *Edouard Morren*, *Celine Forestier*, *Charles Lawson*, *Juno*, *Sir G. Wolsey*, *Mdme. Margottin*, *Mdme. Victor Verdier*, and *Etoile de Lyon*; and amongst Messrs. Paul's best were *Alphonse Soupert*, *La France*, *Beauty of Waltham*, *Perfection de Monplaisir*, *Merveille de Lyon*, *alba rosea*, and *Charles Lawson*. These with Roses staged not for competition produced a strong feature in the show.

AZALEAS. For these plants four classes were provided, and produced numerous finely bloomed plants. Messrs. Van Houtte, of Ghent, also staged a group of finely bloomed standards not for competition, all of which were of great excellence.

HEATHS were contributed by Mr. Cypher and Mr. James. In Mr. Cypher's collection were handsome specimens of *Erica aristata major*, *depressa*, *multiflora*, *Cavendishi*, *Victoria*, *ventricosa coccinea minor* and *ventricosa alba*. Mr. James staged *E. tubiformis*, *Baudouin*, *Cavendishi*, *ventricosa magnifica*, *eximia*, *superba*, and *affinis*.

PERLARGONIUMS, for which three classes were provided, produced keen competition, those from Mr. Turner being marvels of cultivation, more especially the fancies, the finest of which were *Ellen Beck*, *Lady Carington*, *East Lynn*, *Princess Teck*, *Miss E. Little*, and *The Shah*. Fancies shown by Mr. Phillips, Langley Broom, Slough, were also remarkably fine. His best varieties were *delicatam*, *Beatrice*, *Roi des Fantaisie*, and *Vivandiere*. Amongst large-flowered and show kinds notable were *Mdme. Thibaut*, *Flirt*, *Fortitude*, *Lady Isabella*, *Digby Grand*, *Triomphe de St. Mande*, *Amethyst*, *Maid of Honour*, *Prince Leopold*, and *Kingston Beauty*.

HARDY HERBACEOUS PLANTS came from Mr. Ware, Tottenham; Messrs. Paul and Sons, Cheshunt; and from Messrs. Collins & Gabriel, Waterloo Road, London, amongst which we noted good examples of *Trillium grandiflorum*, *Trollius americanus* and *Fortunei fl.-pl.*, *Polemonium Richardsonii*, *Lilium longiflorum Harrisii*, *Saxifraga Camposi*, *Primula Sieboldii*, *Arnebia echinoides*, &c.

ALPINE PLANTS came from Messrs. Collins and Gabriel and Messrs. Paul and Sons, Messrs. Collins having splendid specimens of *Phlox amena*, *Nelsonii*, and *frondosa*, *Aubrieta Hendersonii*, *Gentiana acaulis*, and *Viola Mrs. Charles Turner*. Amongst Messrs. Paul's were *Androsace sarmentosa*, *Menziesia empetriformis*, *Hutchinsia alpina*, *Aubrieta tauricola*, *Pulmonaria dahurica*, *Houstonia cerulea alba*, *Linum campanulatum*, &c., &c. Other hardy plants, contributed by Mr. Ware, were numerous *Montan Paeonies*, the best of which will be found amongst the new plants; a beautifully diversified group of *Primula Sieboldii*. A group of alpine and herbaceous plants from Messrs. Paul contained amongst others the lovely *Gentiana bavarica*, *Myosotis rupicola*, *Papaver nudicaule*, *niviatum* and *album*, *Bellis caerulea*, *Uvularia grandiflora*, *Lithospermum prostratum*, &c.

FERNS.—This class produced three collections, none of which were of great note; in Mr. Douglas's six were *Gleichenia flabellata* and *Spelunca*, *Microlepia hirta cristata*, *Dicksonia antarctica* and *Adiantum concinnum latum*; Mr. Butler staging *Todea africana*, *Dicksonia squarrosa*, *Asplenium inaequalifolium*, *Microlepia hirta cristata*; whilst Mr. Eason, The Gardens, Hope Cottage, Highgate, contributed nice specimens of *Gleichenia dicarpa longipennata*, *Davallia Mooreana*, *Gymnogramma Lanchena*, &c.

FINE-FOLIAGE PLANTS were contributed by Messrs. Cypher, James Offer, Butler and Wheeler, all showing large specimens of *Palms*, *Cycads*, *Crotons*, *Dasyliirions*, &c., all of which were in excellent condition, but amongst which there were no novelties.

GLOXINIAS were contributed by Mr. Eason, but were not remarkable.

NEW PLANTS.—Botanical certificates were awarded to Mr. B. S. Williams, for *Chamaedorea cynicanthus*, *Odontoglossum Andersonianum splendens*, and *Laelia grandis*; to Mr. Cypher, for *Laelia purpurata Cypheri* and *L. p. Wyattiana*; to Mr. J. Hill for *Cattleya Mendeli grandis* and *Cattleya Mrs. Little*; Mr. W. May for *Odontoglossum Jacobiana*. Floricultural certificates.—To Mr. B. S. Williams for *Gloxinia Alfred Outram*; Mr. T. Ware for *Paeonia rosea odorata*, *P. Triomphe de Milan*, *P. odorata Maria*, and *Trollius Fortunei fl.-pl.*; to Mr. C. Turner for *Tea Rose Miss Edith Gifford* and *Pelargonium Magpie*; to Messrs. J. Laing and Co. for *Begonia Prince of Wales*, *B. Queen Victoria*, and *B. Princess of Wales*.

Mr. James received a large bronze medal for a collection of *Dracaenas*; Mr. Ware for group of *Tree Paeonies*. Bronze medals were awarded to Mr. James, Farnham Royal, for a group of magnificent *Calceolarias*; to Messrs. Standish, of Ascot, for a collection of *Japanese Acers*; to Messrs. Barr and Son for a collection of cut flowers; to Mr. H. B. May, Edmonton, for group of *Calceolarias*, *Mignollette*, and *Ferns*; to Mr. Ware for group of *Japanese Primulas*. Certificates were awarded to Mr. J. Walker, Thame, Oxon, for cut *Roses Maréchal Niel*, alike remarkable for size and colour, and to Messrs. Paul and Son for a collection of alpine.

Mr. B. S. Williams, Victoria and Paradise Nursery, Upper Holloway, staged a magnificent group, artistically arranged, in no way crowded, every plant displaying its character and yet all deformity in the shape of ugly pots being quite hidden. The group was composed largely of *Orchids*, interspersed with graceful *Palms*, *Dracaenas*, *Ferns*, &c. Of the *Orchids* the most notable were fine forms of *Cattleya Skinneri*, *Mendeli*, and *intermedia*, *Laelia purpurata* and *grandis*, *Cypripedium grande* and *tesselatum porphyreum*, *Odontoglossum vexillarium*, *Vanda tricolor Patersoni*, and *Dendrobium Wardianum*. Amongst ornamental-foliaged plants notable were *Aralia Kerchovana*, *Sarracenia Courti* and *Plan-*

bean, *Cocos hybrida*, *Lomaria discolor bipinnatifida*, *Lomaria gibba platypetala*, *Gleichenia rupestris* and *flabellata*. Large silver medal.

Messrs. Laing & Co., The Nurseries, Forest Hill, also staged a most effective group, composed of well-grown and well-coloured *Dracaenas*, *Caladiums*, *Palms*, *Crotons*, double and single *Tuberous Begonias*, and numerous *Orchids*. Amongst *Palms* the elegant *Geonoma gracilis* and *Cocos Weddelliana* were conspicuous. The best *Caladiums* were *Triomphe de l'Exposition*, *Mdme. Marjolin Scheffer*, *albo-luteum*, *Ferdinand de Lesseps*, and *Leopold Robert*; *Begonia Queen Victoria*, bright crimson-scarlet, very large, good shape and substance; *Princess of Wales*, rosy-carmine; *Prince Albert Victor*, vivid scarlet; *Princess of Wales*, crimson-maroon, an exquisite flower. Double *Begonias* were represented by *alba rosea*, outer petals rosy-pink, centre ones white; *Lord Randolph*, crimson; *Blanche Duval*, bright scarlet. Amongst *Orchids* the most notable were *Odontoglossum triumphans*, various forms of *Cattleya Mossiae*, *Odontoglossum vexillarium*, *Dendrobium superbum*, *D. Wardianum*, *Odontoglossum citrosimum*, &c. Large silver medal.

Messrs. Cutbush and Sons, Highgate, staged a large bank of *Palms*, *Indian* and *Japanese Azaleas*, *Ericas*, *Crotons*, &c., bordered with *Adiantums*. It would, however, have been better had the space been larger or the number of the plants less, the beautiful *Heaths* especially being far too crowded. The most notable in the group were *Erica Victoria*, *Cavendishi*, *ventricosa*, *coccinea minor*, *perspicua nana*, *McNabiana*, *Aitoniana*, *rubra* and *eximia superba*, *Leptospermum bullatum*, *Boronia elatior*, *Tetratheca verticillata* and *hirsuta*, *Hypocalymma robusta*, various *Kentias*, and *Azaleas*. Silver medal.

A fine group of *Orchids* also came from Messrs. Hugh Low and Co., Clapton, consisting of magnificent forms of *Cattleya Mendeli*, *Mossiae*, and *Reineckiana*, *Laelia purpurata*, with a remarkable lip, large and wholly deep violet-purple, *Cypripediums*, and *Odontoglossums*. Bronze medal.

A group of *Orchids* from Mr. F. C. Jacob, Amherst Park, Stamford Hill (gardener, Mr. May), contained numerous *Odontoglossums*, amongst which were handsome forms of *Alexandre*, *scepstrum*, *Wilckianum*, *Pescatorei*, fine *Masdevallias*, *Cattleyas*, and *Cypripediums*. Bronze medal.

A prize list is given in our advertising columns.

Death of Philip Frost.—We regret to announce the death on the 10th inst., at the age of 83, of Mr. Philip Frost, who has worked so long and honourably at Dropmore, and rendered the place famous for the magnificent collection of *Conifers* growing there. Sixty-five years have now elapsed since he first went to work in the gardens there. He was born at Moreton, in Devonshire, in 1804. At the age of 14 he was employed on Lord Grenville's estate at Bocomoc, in Cornwall, where his father also was. In 1822 he came to Dropmore, where he remained until 1826, when he left for Ashted Park. In the following year, however, he returned to Dropmore, but again, in 1827, he removed to Caen Wood, the seat of Lord Mansfield at Hampstead. Here he remained only a short time, as we learn that he went to the Botanic Gardens at Chelsea, then under the curatorship of Mr. Anderson. In 1832 he returned to Dropmore as head gardener, where he has remained ever since. Mr. Frost has been very successful in the cultivation of *Coniferae*, as the noble specimens, notably those of *Abies Douglasi* (measuring in 1886 124 feet high) and *Araucaria imbricata* (measuring in 1886 63 feet high), testify. In 1872, on his completing his fiftieth year of service, some 200 of his friends presented him with a handsome silver cup, on which were engraved the portraits of the Douglas Fir and *Araucaria*. Accompanying the cup was a purse containing £210, which was invested as a life annuity.

We are pleased to say that the report of the death of Mr. Ford in last issue was an error.

FORESTRY NOTES.

I HAVE been reading that book on forestry which has been described as "the best work on the subject extant," for although knowing both the book and its author well by repute, I have never seen it until now, although I have recommended it to others. No doubt in such a book there is much excellent information. It would be easy to point out the faults in some authors' teachings, but my object in the present case was not to find faults, but to see what such an authority said on some of those subjects lately discussed in *Woods and Forests*. Looking up the subject of hedgerow timber, one is much disappointed to find him decidedly on the "wrong side of the hedge," because he advocates its culture, and no doubt has helped to foster what we and all those most closely interested regard as an evil. Great excuses are to be found for foresters and their employers when we find such an authority as Brown stating that hedgerow trees "instead of being a nuisance to farmers, become of first-rate importance in all well cultivated districts; and instead of impoverishing the land they become a source of fertility to it." This is a statement which when we read it deprived the book of much of its value in our eyes as a practical guide. True, he specifies "hedgerow trees when trained up and managed upon right principles," but when we come to the training and principles, they are nothing better than an apology for the maintenance of such trees and a condemnation of their existence. Two of the main objects of raising hedgerow trees are, we are told, "the raising of useful timber in the country without occupying much breadth of land exclusively for that purpose" (the old fallacy), and "the producing a degree of shelter for stock and crops in the adjoining fields." One cannot believe that Mr. Brown had the ordinary English system of farming with its small fields and numerous hedgerows before him, but rather those big Scotch farms and fields, where the hedgerow timber, even when plentiful, is somewhat excusable, although the best farmed districts even in Scotland seem to have ignored his advocacy of hedgerow trees by sweeping all or most of them away. In that respect our author cannot be said to have had much honour in his own country. His instructions as to the training of hedgerow trees constitute his main, but unwitting objection to their existence. Their training "is a matter of the greatest importance, and should be most perseveringly attended to." This training is to begin in the nursery and be continued there till they are from 6 feet to 8 feet high, and afterwards the training is to be so unremittingly attended to that one wonders where the expense of culture is to come from when the trees are felled for timber and sold. As to the other advantage, viz., shelter for crops and stock, the trees are to have "a clean stem of from 10 feet to 15 feet high," and as the trees grow, their branches are to be shortened well in so that they may ultimately extend only "a few feet over the fence upon each side." Now, where is the shelter to come from to either crops or stocks from a straggling line of trees with bare stems 15 feet high? The very behaviour of cattle tells any rural observer that shelter is only afforded by bushy fences made thick and dense to the bottom and not by long limbed trees whose long shadows fall upon the crops soon after noon and deprive them of the sunshine when there is any. It is but right also to state that Mr. Brown's advocacy of hedgerow

trees appears to have been prompted at the time by the advocates of improved agriculture "crying out vehemently against hedgerow timber, declaring to an enlightened public that all hedgerow timber trees are injurious to the raising of plentiful and healthy crops," to quote the opening passage of his chapter on the subject.

THINNING.—Turning to this subject, we are sorry to find the same author making assertions so totally at variance with facts as greatly to surprise the reader who notes the stress Brown lays on foresters at all times making careful personal observations in everything pertaining to their duties. For instance, on the subject of thinning plantations we are told the Silver Fir and Spruce are both "extremely impatient of want of space," and that "the more the branches are encouraged by having space, the larger and better is the timber of the trees;" whereas exactly the contrary is the case, the one great fault of our home-grown Spruce being that it is too rough and full of knots, produced by giving the trees space to make too many branches. That is a fact that the foresters of Brown's school have begun to realise lately. It is very amusing, a few pages further on, to find the author of this advice in regard to Firs asserting that in a state of nature the Pine family is generally found in large masses of each species separately, and that "there" (in a state of nature) "we always find the best timber of whatever kind," a complete contradiction of the former assertion, that Firs produce the best timber that have room to produce the most branches, because in a state of nature the Firs seldom produce more than a tuft of branches at the top, as being self-sown and springing up thickly and remaining crowded, like seedlings in a hot-bed, they never can grow in any other way. The last statement was, however, made after the author had visited the natural forests of America; the first, about the Spruce, we may suppose was derived from another source previously. In another part of the book we are told that Fir and Pine trees, as a general rule, should, where grown for timber and shelter, be left "about the third of their height" asunder, that being the distance "found most favourable to the useful development of the Fir and Pine tribes as timber trees." As elsewhere the author tells us the taller Firs and Pines grow from 80 feet to considerably over 100 feet, it follows that a third of the height runs from nearly 30 feet upwards; whereas we know from common experience that half that room will produce most excellent Fir and Pine timber of generally useful size, and much more to the acre, while in a state of nature less room still suffices, we are assured by travellers. I have read and been told that Brown's "Forester" has done more to influence British, and especially Scotch, forestry than any other book, which I do not doubt, and these are some of the things I have culled from it, and I leave them to be judged in the light of recent discussion on these topics.

UNTHINNED PLANTATIONS.—Though not denying the advantages of thinning in certain cases, I am inclined to think that leaving thickly-planted young plantations altogether unthinned till they grow up to timber size is not fraught with such disastrous results as foresters generally assure us. I admit that the artificial regulation of the trees may make the evenest plantation, but I would not undertake to say that such a plantation would produce the best, heaviest, and most valuable crop of timber in the end. No British forester has yet been able to dispute that the very kinds of trees he grows at home with such care produce timber of the very best

quality in climates no better than our own, where they are left unthinned and so crowded that it becomes a struggle for existence among the individual trees, but always ending in an even, regular, and heavy crop of fine timber over vast tracts. Why should not the same thing happen here, and why thin, at all events in those cases when it only adds to the cost of culture? I looked through a plantation of Sycamores yesterday that were, I believe, sown about thirty years ago, and must say that although the plantation has never been thinned I never saw a more regular or better crop of trees, mostly now about 30 feet high or more, and big enough for bobbin-wood purposes and the like, every tree as straight literally as a ramrod, standing as they do not much more than 6 feet or 7 feet apart—that is, the large trees. They have been thicker on the ground than that originally, but a natural process of thinning has been going on, resulting in the smothering of the weakest, of which plenty are still standing, some long dead and others not far from it, but leaving the stronger trees perfectly regular and strong and much thicker on the ground than the artificial thinner would have left them, forming a uniform and dense leaf canopy overhead—making it so dark beneath that even the Grass has ceased to grow in most parts. This plantation stands on a hill-top, and when seen against the sky-line in winter, as the traveller approaches, the crowded mass of straight poles, standing like a solid battalion, has a very striking effect. This natural process will go on, and I have no doubt in the end the result will be a fine crop of Sycamore of the best quality.

MISMANAGED PLANTING.—I think if "Rusticus," in *THE GARDEN* (p. 455), is fully convinced that he has "planted ten Corsican Firs" for every one planted by "Yorkshireman," and that in most cases his ten have mostly died off, "no matter how careful the operation of planting is performed," then I submit that he has planted sadly too many in his time, and his failures must be frightful to look back upon. I did not condemn transplanting either, as "Rusticus" conveys, but only said that roots were of no value if not got up with the plant; hence our care in seeing orders executed ourselves. As to "Rusticus's" question, if I ever saw a Spruce Fir with a tap root, my reply is that I hardly ever saw a young tree without one till it had been lost by transplanting.

Wood of the Black Walnut.—The timber of this valuable North American tree is, on account of its durability and other good qualities, adapted for almost every kind of woodwork. It may be used for the largest and most costly kinds of furniture, as well as for carvings of the most elaborate kind. It is used for doors exposed to the full action of the weather; for conservatory doors, exposed to constant damp and considerable changes of temperature; for internal doors and casement windows, of rather large and costly construction, and carved, and for every kind of small cabinet work, exhibiting the highest taste and good workmanship—for all these purposes the wood answers most admirably. It appears to bear rough external wear quite as well as Oak. It does not warp or crack like Oak, and bears the greatest transition of heat and cold without any visible change. The colour of the wood, when oiled, is perfect—that natural rich brown colour which three centuries of wear will alone give to Oak. It has a close grain, without much figure; it is thoroughly well adapted for every kind of carving; and its cost now is not higher than Oak. It has every possible advantage over Oak, and in old cathedrals requiring new stall-work its rich brown colour would give it a great advantage over the pale brown-yellowish hue of new Oak, which to

most persons is most offensive. No doubt want of knowledge of its many excellent qualities has alone prevented the more general use of Black Walnut wood. Without question it would be a safe investment to plant the Black Walnut largely in this country, now that its timber has been proved to be so valuable.—Z.

THE MEXICAN DECIDUOUS CYPRESS.

(*TAXODIUM MONTEZUMÆ.*)

THIS is a pretty but little-known tree, one that is described in all plant lists and Conifer books as too tender for the climate of Britain, and one that, moreover, has stood unharmed for many years at Penrhyn, has attained a height of 40 feet, and is one of the brightest ornaments in the small patch of well-sheltered and choicely-planted ground where it grows.

I know of no other Conifer that is so delicately beautiful as the one in question, none that in autumn changes to such a lovely golden red its light, fresh, green foliage of the summer, and none that is better fitted for adorning a shady, well-chosen spot on the lawn of some maritime garden. The Penrhyn tree, the only really established plant of the Mexican Cypress that I have seen, is of pleasing outline, the spread of branches being small in proportion to the tree's height, remarkably uniform, much ramified, and nearly horizontal. It is growing in a sheltered corner with a southern aspect, and in soil composed principally of a second-rate, but dampish loam. The Pomegranate, Myrtle, Azalea, Lapageria, Chamærops, and Cunninghamia are its near neighbours, all of which stand the rigours of our Welsh winters with admirable pluck and without the shadow of harm; indeed, save the Lapageria, I have never seen either a bast mat or covering of any kind placed around them, so self-confident is our worthy gardener that they are perfectly able to take care of themselves. This is merely mentioned so as to give an idea of the genial warm corner in which the so-called tender Mexican Cypress is growing.

The stem of the tree in question is straight and well formed, 42 inches in girth, and with bark of a cinnamon-brown—not rough nor smooth, but a medium between the two. At a considerable height from the ground the trunk divides into two limbs, these growing perfectly parallel and within a few inches of each other for a number of feet, the branches spreading regularly around and covering a space of 16 feet in diameter near the ground-level. The Mexican *Taxodium* may best be described as a very refined deciduous Cypress, the foliage being finer, of a lighter green, and the whole tree more graceful in appearance; leaves arranged in two rows, long, pointed, and of pea-green colour. The wood, from the small specimen I had the chance of examining, is light, but strong, and nicely grained.

To recommend this tree for planting in any but the warmer parts of England and Ireland would perhaps be out of place, but I must say, in judging from the fine specimen here, and which has never suffered from the effects of frost, that I am quite convinced that the tree is not nearly so tender as it is described. It likes a cool, damp soil, by the water's margin, in this respect resembling its near relative, *T. distichum*.
A. D. WEBSTER.

Canadian forests.—The soil of the eastern townships is very fertile and susceptible of the highest degree of cultivation. The features of the country are rolling, having the appearance when viewed from an elevation of an upheaval of an immense wave suddenly stilled; and these slopes and valleys, before they were cleared, were covered with a luxuriant growth of those kinds of forest which in America are known as a sign of naturally drained soil and great fertility. There are many kinds of wood found in the eastern townships forests. Among these the following may be enumerated: Maple (hard and soft), Birch, Elm, Ash, Spruce, Bass-wood, Butternut, Hickory, Cedar, &c. It is also to be noticed that contiguous to these woods are numerous water powers which may be utilised in manu-

factures. The country is literally intersected with streams and rivulets, the waters of which are cold and clear and the home of the red trout. In the north-west territory of the province of Manitoba nearly the whole of the fences are composed of posts of Spruce and Poplar, the latter of which, with the bark removed, will last twenty years. Pine and Bass-wood timber are also used, the former ranging from £4 to £12 per 1000 feet. Poplar and Oak are in sufficient quantity to supply the present demand, but it is feared there is not enough to supply a very large population, in which case there might be a scarcity of hard wood, but plenty of Poplar and Tamarac, the former of which is produced very rapidly. Coal is not known to exist in the province of Manitoba, but is said to be found about thirty miles west of the boundary of the province. In the Peace River country five-sixths of the timber is Poplar. Balsam Poplar is very abundant on the islands in all the north-western rivers, often attaining a diameter of from 6 feet to 10 feet. White Spruce grows to a very large size on all the water sheds and slopes of the south bank of the Peace River, on islands in all the rivers, and very abundantly on the low lands at the west end of Lake Athabasca. It is frequently seen over 3 feet in diameter, but the usual size is from 1 foot to 2 feet. White Birch is not abundant along the Peace River, but is common on the Athabasca and Mackenzie Rivers. The Northern Indians make large quantities of syrup from its sap in spring.

PRUNING HARD-WOODED TREES.

ALTHOUGH the pruning of forest trees at one period or another becomes necessary, it is a fact that this branch of forestry is too often neglected, or but performed in an injudicious and unsatisfactory manner. This circumstance is not surprising when it is considered to whom, on many estates, the so-called management of the woods is entrusted. Even where experienced men are in charge, their operations are often hampered by inexperienced persons, or suffer from the want of means for properly carrying out the work when such becomes necessary.

There is no doubt that if hard-wood plantations are judiciously managed, the amount of pruning that becomes necessary is reduced to a minimum, but there are always subjects that require to be operated upon in the way of pruning on every estate; therefore, it is desirable that everyone who has the charge of plantations should possess the necessary knowledge of when and how to proceed when pruning is required. The object of pruning trees intended for the profitable production of timber is to regulate their growth, so that a maximum amount of sound marketable timber is produced. That, of course, will be materially assisted by judicious thinning, and the work of the pruner in this case should be directed in gradually enlarging the length of the stem by removing the lower branches and regulating the top by cutting out superfluous leaders and shortening at a horizontal twig all lateral branches that are assuming unusual vigour. Where thinning has not been carried out on a system calculated to obtain the foregoing results, hard-wood trees will have acquired greater lateral vigour, at the expense of the upward growth. If pruning has been neglected, it is desirable to proceed cautiously, and remove but a limited number of the lower branches, and shorten at a lateral twig a few others, leaving for a future pruning their complete removal. The top must also, if necessary, be operated upon by removing or shortening all contending leaders, retaining only the most central and vigorous one. All lateral branches, moreover, which have outgrown their neighbours, or are likely to cause the tree to become one-sided, should be shortened, but too much ought not to be done at one time, or the cure would be probably worse than the disease. The process should be repeated every second year, so that the object aimed at may be gradually, instead of quickly, brought about, the idea being to prune gradually instead of carrying it out all at once. Severe pruning results in the arrest of the flow of sap and the production of an undue quantity of spray

or shoots in the vicinity of the wounds, and frequently on the stem itself, so that the tree not only becomes unsightly, but the growth is checked, and often several years elapse before it recovers its original vigour.

Ornamental trees, on the other hand, do not, as a rule, require much stem-pruning, but it is essential that their tops should be attended to, so that they may be induced to develop a well-proportioned and evenly-balanced head, and be less liable to be damaged by high winds. The leaves of a tree being such important organs, it is necessary, in order to maintain a vigorous health, that trees should be well furnished with healthy foliage; consequently, in pruning the object should be to defoliate the trees as little as possible. Opinions differ as to the best season for carrying out pruning operations, but it better be done at any period than not at all.

S. A.

The Carolina Poplar.—This old acquaintance, and the best of the Poplars for use as a shade tree, or for its wood, has been generally known as the Black Italian Poplar—"black," because its foliage is of a deep rich green, and dense; and "Italian," because, having been taken to Europe at an early date, and being easily propagated, its peculiar merits for street and road planting caused its extensive use in Italy and Germany. In many places where no fences are used, and the country is nearly bare, the lines of road are rendered visible for miles by these Poplars which grow along their sides.

Preservation of wood.—A section of a piece of timber impregnated with tar shows that the conserving substance has followed the lines of the longitudinal fibres, and the microscope often reveals the complete filling of the pores, and every channel which might give entrance to deleterious agents is plugged by the tar, which, in many cases, is also found a perfect preserver of bolts, screws, and nails. It must be clear that no such results as these could be attained without a careful selection and preservation of wood in the first instance. Then it becomes a question as to what is the best preserver, regard being had to cheapness. Is it carbolic acid, or tar, or what? The answer may most materially affect the application of wood where durability is an absolute necessity to its adoption.—X.

Draining land.—There is no doubt that stagnant water in land is most injurious to vegetation, and although it may be ever so fertile, no crop of any value can be produced by it when in that condition. Its effect upon pastures is to encourage the growth of a number of semi-aquatic plants, which are devoid of any useful property, and they and the dampness combined tend in many instances to engender unhealthiness and disease in those animals which graze upon them. The surface layers of soil in a healthy state are more or less in an open and porous condition, so that air and the essence, so to speak, resulting from the decay of organic matter are freely percolated through them. It is necessary for the healthy growth of plant life that the soil should be in this state in order to prepare new supplies of fertilising matter for their absorption. Should the land, however, be in such a state that its interstices or air passages are filled continually with water, it is evident that the requisite alterations cannot take place. It is therefore necessary to resort in these cases to a system of drainage, so as to draw off all superfluous water that may be lodging in the soil, and thereby promote a means by which the water falling on the surface may pass away freely. Among other beneficial effects consequent on draining is that the sun has a more direct influence in imparting heat to the soil, thus raising its temperature, which results in vegetation being forced earlier in the season and in hastening its growth. The soil is also brought into a fit state for being benefited by the application of manures, which, if laid on those in a wet and undrained condition, would have but a slight influence upon them, and after the drainage of pastures the inferior Grasses gradually disappear, which are replaced by others of a richer and more abundant character.—A. S.

No. 810. SATURDAY, May 28, 1887. Vol. XXXI.

"This is an Art
Which does mend Nature: change it rather; but
THE ART ITSELF IS NATURE."—Shakespeare.

NOTES FROM THE ISLE OF WIGHT.

As you invite contributions, I will send you mine, promising only that if a sailor looks at his worst when he has just escaped shipwreck by the skin of his teeth, so these flowers, it should be remembered, have been buffeted about during the last week or ten days from every point of the compass, and are now the mere relics of what they would have been in any ordinary spring. Still, we can be happy to-day. There is at last a reminder of the merry month of May. It has not slipped us entirely, and everything will soon pluck up courage again. For Irises, I am more than thankful that there is a professor of them at Cambridge, and what is more to the purpose is the fact that he remembers me most kindly and liberally. If it were not for that and the raid which I made last year on the Privat Botanischer Garten at Baden-Baden, my garden would be comparatively naked and destitute. But Irises now gravitate here in very fair number, and, to my happiness, stay here. Already, not a few have had their days of glory, and their pride is over for this year. *Iris arenaria* is one of them, and I was very much pleased with it. *I. susiana* succumbed to the tempest of last week, but you can still have a bud of it, and it is sure to open in water. It is the same with *Xiphion tingitanum*, which is very handsome, and was kindly given to me by Mr. Wolley Dod. I enclose his *Bludowii*, which I never saw till just now: the black veining on a clear yellow ground gives it a very striking appearance. *I. statice*, *I. balkana*, *I. subbiflora*, *I. iberica*, *I. Tolmieana*, *I. Redoutei*, *I. cristata*, and many others are all in different stages of beauty, either promised or fading. You will hail with acclamation an old friend, *Iris pavonia*, again. It is one of the delights of the year, and I espied it just now for the first time. I am thankful to say that the late Mr. Mangles distributed his favours very equally between Guernsey and the Isle of Wight, and as with Mr. Smith so with me *Rhododendron Aucklandi* is glorious; the extreme delicacy of the blossom is wonderfully set off by the large pink-tipped buds, and, standing as it does in a bed of some of Mr. Waterer's very best hybrids, it looks like a princess amidst a galaxy of washerwomen! Mrs. Clutton and such like are nowhere by its side, and a kind old friend here with whom I have been quarrelling about flowers for twenty years is obliged to confess at last that for once he is beaten. If other *Rhododendrons* bear any comparison at all with *R. Aucklandi*, I hope in four or five years' time to have something to show here. Mr. Thiselton Dyer was so good as to let me have twenty-four young plants to experiment on rather more than a year ago, and of these I can report that twenty-three are doing well. I enclose a bit of *Oxalis enneaphylla*, which I like very much. It is a great thing for an *Oxalis* to be neat. *Eremurus robustus*, *E. Bungei*, *E. spectabilis*, and two or three others will be at their best during the week, but I cannot find it in my heart to send them to you. For some reason or other which my gardener and I cannot make out, *Camellias* in the open have done well this year, as they have never done before.

Usually some two or three have done duty for all the rest, but this spring nearly all of them have simultaneously burst out into a full chorus of praise. The note of "K." about *Tulipa Greigi* in your last impression puzzles me a good deal. My experience differs wholly from his. I failed to blossom it very often till I was told by Mr. Horner to take it out of the ground on Midsummer Day and to replant it somewhere about Lord Mayor's Day in November. I scrupulously followed his advice, and I have been recompensed for my trouble. How odd it is that experience should vary in this way, but it is not uncommon with flowers. I suppose that some one little thing disarranges all the rest, and so general rules cannot safely be laid down. Still Mr. Horner must live under very different conditions from mine, and I say Amen to all that he told me about Tulips. *Tulipa Kolpakowskyana* has been an object of great admiration, and *T. altaica* should, I think, find a place in every collection on account of its earliness. Calochorti call for no trouble here: they do well on the rockwork or in the open border without any attention whatever. I enclose two or three—*C. Mawianus*, *C. Leichtlini*, and one other. My present anxiety is about a Rose, and I shall be thankful to any of your readers who can speak from experience and say what ought to be done. I have already applied to several of the best Rose doctors, but they do not give very certain replies. The Rose I allude to is *Rosa berberifolia*, not *Rosa berberifolia* Hardi, which cheated me at first—in the culture of this there is no great difficulty—but *Rosa berberifolia*, which is not very often met with, and which seems to elude cultivation. This precious specimen was given to me on the Continent last year, and I have kept it in a pot for eight or nine months in the greenhouse, but now comes the critical juncture. My gardener thinks it is doing so well as it is I had better leave it alone, but he has never had this Rose in his hands until now, and Herr Max Leichtlin told me last year that it must have root-extension, and that without that it will die, so I am puzzled—I am afraid of putting it in the open border, and I am afraid of leaving it as it is. Mr. T. W. Girdlestone (who has won his spurs so well in the matter of Roses and who must have had his first lessons here when his father was Vicar of Ryde) suggests that it should be planted out and taken back into the greenhouse in winter. Mr. G. Paul once lost this identical Rose, and he does not, therefore, speak positively about its requirements. On the whole, I am left much in the dark about this difficult subject, and when I add that Herr Max Leichtlin cannot grow it, it may be said, perhaps, there is no cause for wonder about that. But certainly at this present moment *Rosa berberifolia* is doing well in my greenhouse. What the chances are of its being there or in my garden next year, I should not attempt to say. We are scarcely out of April yet in very many respects if the ordinary pace of the seasons be considered.

H. EWEANK.

P.S.—May 26. A beautiful flower has opened this morning—*Camassia Leichtlini*; it is of the softest primrose colour, and too much cannot be said in its praise.

Primula japonica.—This, as we saw it the other day in what is known as the wild garden at Kew, is certainly a noble plant, and seems to be perfectly at home here among the tall Grass and old flowering stems of the Imperial *Fritillaria*, with a background of the giant *Polygonum sachalinense*. The bed, if it can be called such, contains some forty or fifty plants. It is perfectly hardy,

having withstood the last severe winter, and we could see the ground covered with myriads of seedlings, which tell a tale of their own about the suitability of this plant for purposes of naturalising. The colour, too, of the flowers when grown out of doors is much more vivid and striking than when seen under glass. Near by, the *Gumera scabra* is doing its best to cover all the available space, and behind is a large colony of the Poet's *Narcissi* just opening and promising a fine display a week or so hence. They are planted in the Grass, and the fresh green groundwork sets off the glaucous leaves and handsome flowers to the best advantage.—K.

FLOWERS IN THE HOUSE AND EDITOR'S TABLE.

Under this head we propose, during the present season of flowers, to notice things, from whatever it partment, that are pretty and useful for the house. Any reader who will help us by sending fitting things, or a word about them, will oblige. The simplest things from the smallest garden, and even from the woods and fields, need not be excluded.

LILACS FROM TROYES.—Again some beautiful Lilacs from Troyes, carrying to London their delicate odour. One called Lucy Ballet is peach colour. When nurserymen name things after their children or their wives, the plants are, we notice, more than usually interesting! Messrs. Ballet also send *Ville de Troyes*, of a purplish hue. Naturally these things are seen far from their best.

*

MITRE-WORT (*Tiarella spicata*).—How beautiful the white spikes of flower rising from a ground-work of satiny deep green leaves veined and washed with reddish brown! The above will be found very useful when used as a carpet under bolder and larger flowers, or for filling up blank spaces between shrubs.

*

RICHARDSON'S JACOB'S LADDER (*Polemonium Richardsoni*).—This useful, though common, border plant is now in flower in many places. It is to hand from Mr. T. B. Field.

*

FAIR MAIDS OF FRANCE (*Ranunculus acontifolius*) is a beautiful plant of about 18 inches high, forming dense masses which are quite covered with little rosette-like blooms of pure white. It will be found invaluable in arrangements of cut flowers. From T. B. Field.

*

WHITE TUFTED PANSIES.—I sit at my window and look out upon a variety of garden plants very striking, amongst which just now is a number of large broad plants of white *Violas*, seedlings of last spring, from Mrs. Gray, and now perfect bunches of pure white flowers. These are really tufted Pansies, clusters some 15 inches over, and like lumps of snow lying on the neutral tinted soil. Some are even better than is the parent; some are inferior, but all are lovely. I have propagated cuttings from a few of the purest and best.—A.

*

ANEMONE CORONARIA.—A big bed of these blooming freely; the blooms, not so large as in previous years, give welcome and effective colour. The plants stood the winter well until March, when the last visitation of snow with horrid London fogs cleared off all the foliage, and effectually checked growth for several weeks. Thus my *Anemones*, usually so early, are fully a month later in blooming this season, but are very beautiful all the same. Seed for a new batch has already been sown, and is now fast coming up.—D.

*

HONESTY.—In one place a big patch of the white, and in another the rich deep purple

Honesty commands attention. The purple is rather the dwarfier of the two, and is much more so than is the old pale purple kind, but which the deeper-hued one has displaced. Sometimes I find flowers to come flaked with white, evidently the product of intercrossing, and then invariably the plants are rather dwarfier than are either of the parents.—A.

*

GIANT POPPY.—How fine and effective is the tall and handsomely cut foliage of *Papaver orientale* as seen in a big clump of a couple of dozens of strong plants. Did not this grand perennial produce such glorious flowers, it would be worth a place in gardens for its fine leafage. The earlier buds are just about to open on some plants; others show no evidence of bloom yet, so that the flowering period is lengthened.—D.

*

WHITE OLEANDER.—The enclosed white Oleander, although not new, I think is very beautiful and worthy of being noted. The plant requires a good supply of water in the season of growth, a soil composed of loam, light manure, and sand, and plenty of light. It flowers freely, and the flowers last fresh five or six weeks.—W. W., *Crews Hall*.

** A very fine spike. We think that these plants ought to be more grown than they are. As small specimens they will be found most useful when in flower, there being such a variety of colours both of the single and double forms.—ED.

*

WOODRUFF.—One of the prettiest little flowers in bloom at the present time is the common white Woodruff, which is now a complete sheet of delicate white blossoms. It grows freely among stones, and does well elevated on banks or around tree stems and shrubs. Once planted, it is no more trouble, as it springs up ever year more beautiful than before. Anyone searching for a good carpeting plant for turning unsightly places into really beautiful spots should make a note of this pretty native plant.—J. G. H.

*

MIXED LILAC BUSHES.—The common Lilac is now loaded with bloom, and I find the beauty of both the common and white kinds is much enhanced when they are planted so that the branches mingle together, and look like one bush. The white kind runs up and flowers best on the topmost growth, being of a more erect character than the purple kinds, and if planted so that the white towers a little above the others, they look really beautiful. The dwarf-growing Persian and Siberian kinds that flower so freely in a small state make capital outer edgings to large groups of strong-growing kinds. A large clump or group on a lawn is one of the prettiest things in the way of flowering shrubs that one can add to the garden.—J. G. H.

*

DOUBLE BORDER NARCISS.—Those who have to provide a supply of cut flowers and depend a good deal upon what may be had in the open air should grow the following three forms of double Narciss, viz., *incomparabilis plenus*, and what are known in the Dutch lists as Orange Phoenix and Sulphur Phoenix. They are cheap, late-flowering, very free and showy, and do well in the open border. Add to these poetic ornaments and the double white, and a most useful group is provided.—R. D.

Patches on Grass land.—I have 4 acres of park land behind my house planted with large trees. The Grass has got into patches of rank and good Grass, showing a very uneven and ugly surface. Neither cattle nor sheep will eat down the patches of tall rank Grass. How am I to deal with this Grass and get the meadow smooth and park-like?

To cut out all the rank Grass would be a very serious undertaking. (I have mown the Grass well during the last two years.—F. MANSON.)

PROPAGATING.

HYDRANGEAS.—These flowering shrubs strike readily enough at any time during the growing season, and where the beautiful and now popular *H. paniculata grandiflora* has been grown in pots and forced into bloom, the shoots of the current season's growth will be now in a suitable condition for cuttings. If they are cut into lengths of from 4 inches to 6 inches, and inserted in pots of sandy soil, they will strike root in about a month if kept close and shaded. They strike better without any artificial heat, or, at all events, with but a very slight amount, as they are, when soft and delicate, liable to the attacks of red spider and mildew, either of which greatly disfigures the foliage. The plants of the common *Hydrangea* that flower in a dwarf state and carry but one head of bloom are struck later in the season, and are formed of the ends of the shoots taken from plants that have been grown under conditions favourable for flowering.

CLEMATIS INDIVISA will be now in active growth, and the young shoots will strike root without difficulty, provided the weaker short-jointed ones are chosen. They must be kept close in a gentle heat till they root, and under the same conditions the beautiful garden varieties of Clematis will also strike. Besides this, all of them—*C. indivisa* included—can be grafted on to pieces of the roots of the Traveller's Joy (*Clematis Vitalba*) in the manner detailed earlier in the season. Of the hardy kinds, the warmer and more sheltered a position the shoots are grown in, the better they will strike.

ACCUBAS.—The berries of these shrubs will now commence to get discoloured, and some will likely drop. When this happens, the berries may be gathered for sowing, provided young plants are required. Should there be but a few berries, they can readily be cleaned from the pulpy matter by hand and sown in a pot or pan, but where there is a large quantity they may be placed in a heap with some sand for a time before sowing. When the seed is sown in the open ground, a spot not too much exposed to the sun should be chosen, as the young plants (like specimens of a mature age) make more rapid progress when somewhat shaded. By far the better way, however, is to sow the seed in a frame, as a more regular state of moisture can be maintained, and germination is much assisted thereby. When in the open ground a few Spruce branches or something in that way should be laid over the bed to protect it from wind and sun.

BERTOLONIAS AND SONERILAS are well-known stove plants with beautifully marked foliage, and some of them require a considerable amount of care, not only in their propagation, but also in their culture. *B. superbissima* and *Van Houttei* are about the most particular in their requirements, but they can be propagated (though not without great care) by cuttings of the shoots or by single eyes. The present is a good time for the operation, as they are now in full growth, and are not long in forming roots. Where there are plants set aside for propagating from, the top of each will furnish a good cutting, and the remainder of the stem can be cut up into single eyes. The soil best suited for the propagation of these things is peat, loam, silver sand, and pounded charcoal, the whole sifted through a sieve with a quarter of an inch mesh. The cuttings should be put singly into small pots, which must be thoroughly drained, and then fill the pot with the before-mentioned soil. When the hole is made for the reception of the cutting a little dry silver sand can be placed therein, and when the cutting is put in position a little more may be sprinkled in the opening before the soil is pressed firmly around the cutting. The remainder of the stem is cut up into single eyes by dividing it immediately above each joint, and then splitting the stem down the middle, thus leaving an eye and a leaf to each. These single eyes are then put in the same way as recommended for cuttings, and inserted to such a depth that the bottom of the bud is on a level with the surface of the soil. Each

leaf should then be secured to a stick, otherwise, owing to the slight hold of the soil, the cutting is very likely to fall out. After this a thorough watering through a very fine rosed water-pot must be given, and the cuttings allowed to drain a few minutes before placing them in a close case. The case chosen for their reception should have a gentle bottom heat, and be quite free from drip. The great thing to guard against is damp, and to prevent it as far as possible great care must be taken in watering, shading, and occasionally in giving a little air for an hour or so. The best time for this is the first thing in the morning. Seeds of some kinds are often obtained, and to succeed with them they must be sown in well-drained pots or pans, using for the purpose much the same kind of soil as recommended for cuttings. The pots must be filled nearly to the rim with soil, and being pressed down smoothly a thorough watering should be given. While the surface is still wet the seed may be sown thinly thereon, and just slightly sprinkled over with silver sand. The pots must then be placed in a case as for cuttings, and if plunged in a gentle bottom heat so much the better. When the seeds germinate a little air must be given, and the young plants pricked off when large enough to handle.

PERNETTYAS.—Where these ornamental-berried shrubs have been in fruit throughout the winter, many of the berries will have lost their freshness and may now if need be gathered and sown. The berries may be rubbed up with a little dry sand and sown at once, either in pans of sandy peat, or where there is a considerable quantity a frame may be set apart for them, and 5 inches or 6 inches of soil being placed therein, the seeds may then be sown. Whichever plan is adopted, the shelter of a frame must be accorded them, and it is better if kept close and shaded from sunshine till the young plants make their appearance. When large enough they may be pricked off, and will make more rapid progress if still sheltered by a frame during their earlier stages. Of course, plants raised in this way cannot be depended upon to perpetuate any particular variety. When it is necessary to propagate any of the named varieties, other means of increase, viz., by cuttings, layers, and division, must be employed. Cuttings may be formed in early summer of the current season's shoots, when they commence to acquire a woody texture. They must be cut off at a joint, and a few of the bottom leaves having been removed, they should be then dibbled into pots of sandy peat. It is necessary to drain the pots thoroughly for the reception of the cuttings, and to press down the soil very firmly. When the cuttings are put in securely and a thorough watering given to settle the soil, the pots should be stood in a close frame, and kept shaded from the sun till they root. They strike quicker and in a more satisfactory manner if covered with a bell-glass, for the double protection of a frame and bell-glass as well tends to maintain the soil and cuttings in a more even state of moisture. They will take a couple of months or more to strike, and the better way is to leave them undisturbed in the cutting pots till spring, when they can either be planted out in a prepared bed, or potted off and when established planted out. This last is, generally speaking, the better plan, as the hair-like roots are so delicate that when transferred from the cutting pots to the open ground, some of the more tender are very likely to succumb. Layering may be carried out at any season, and may be frequently done without detracting from the appearance of the plant in any way, as the low growth of these *Pernettyas* renders them easily brought in contact with the earth. They may be layered in the ordinary manner, that is by just cutting a tongue on the lower side of the branch in the part that will be covered with soil, and pegging the branch securely in position. Division is but a modification of this last, as plants that have been buried rather deeply in the soil will in many cases have produced roots from the underground portion of the branches, and the plant can sometimes be split up into several pieces, or single branches be detached with sufficient roots to support them. The better way is to plant them at first in a sheltered position, and when they become established they can be removed to wherever required. T.

FLOWER GARDEN.

NARCISSUS CYCLAMINEUS.

This curious and rather pretty form of *Narcissus* may be called a re-introduction, and has been several times brought before the *Narcissus* Committee of the Royal Horticultural Society during the present season, and much difference of opinion as to its parentage has been expressed, though there seems to be no doubt that *N. triandrus* blood is in it. Perhaps when it has been under cultivation a little longer the doubt may be cleared up. It is an elegant and curious little plant for a pot, and its cultivation under protection is perhaps the best for this and for all the section, which require more sun than is usually their lot in England.

Mr. Tait, of Oporto, distributed bulbs of *N.*

Narcissus cyclamineus. Engraved for THE GARDEN from a coloured drawing sent by Rev. A. Rawson.

cyclamineus to several persons in this country during the last autumn, and it is to him that I am indebted for those which produced the blooms represented here, as well as for some other curious forms of *Narcissus* collected in Portugal. A. RAWSON.

Tree Pæonies.—Though the cutting winds and late spring frosts often work such havoc among the Tree Pæonies when planted in the open ground, yet a slight protection will successfully bring them through their most critical stage. A great point in their favour is that they readily lend themselves to pot culture, and on that account may be employed for the embellishment of the greenhouse at this season, and will make a goodly show therein. The Tree Pæony will not succeed with hard forcing, but with no more protection than a cold frame, is now in flower; and some plants that were taken into a

gentle heat about the middle of March were in bloom more than a month ago. A good and, at the same time, holding soil is necessary for these Pæonies, a very suitable compost being good fibrous loam with an admixture of well-decayed manure. —T.

PLANTING DAHLIAS.

MAY is the month for planting out Dahlias, but of late years it has hardly been safe to do so until the first week in June, and so it has been found much better to grow on in pots any choice varieties, so as to get them as strong as possible before planting them out. There are great advantages in doing this, especially, as sometimes happens, when at some flower shows Dahlia blooms are invited as early as the first week in August.

It was an old custom on the part of those nurserymen who grew Dahlias largely for sale purposes not to send out any plants until the 1st of May, and

when the days have lengthened and the weather is warmer, they will make roots in about three weeks, and so the work is greatly hastened. By and by, when the cuttings have rooted, they are potted singly into 2-inch pots, placed in a frame heated with manure, and when established gradually hardened off and then placed in cold frames ready for sale. Thousands of plants of Dahlias in these tiny pots are annually sent out to all parts of the country, carefully laid down on their sides and packed with soft Moss in square or oblong Willow-made hampers. It is surprising how well they travel and what very little harm falls to them on the way to their destination.

Those who grow Dahlias for exhibition purposes generally trench their ground in autumn and throw it up in ridges for the winter; it is then levelled in March or April and well dug over previous to planting. When planting time comes, the ground is marked out, and the usual practice is to plant 6 feet from row to row, and the plants nearly the same distance apart in the rows. This gives ample space for development, and room is afforded for the grower to get round his plants at the blooming season. The plants should always be far enough apart to prevent the branches from being drawn.

Unless the ground was well manured in the autumn and it is poor, some manure should be put in the soil at the time of planting. Let a hole be dug, two or three spadefuls of well-decomposed manure thrown in and well mixed with the soil, and then planting can be done—turning the plants out of the pot, carefully loosening the fibres, and, in the act of planting, placing about the roots some fine waste soil from a potting bench, in order to give the Dahlias a good start. As a hint to planters, it may be stated that the best plants are those that are short, stout, and fast swelling in the main stem. Those that have been too long in the pots take on a stunted appearance, the main stem becomes hard, and they do not make a generous growth; hence we see the advantage of potting on Dahlias when they come from the nursery in 2-inch pots, as it helps a free development and stunting is avoided.

When planted, secure each plant to a stout stake, allowing ample space for the stem to swell. Those who grow for exhibition add two small stakes at right angles, to which the plant is also secured, and by these means it is kept in a firm position during rough weather. Large stakes are added as the plants advance in size, and the side branches are firmly secured. High and sweeping winds do great damage among Dahlias, and if not secured as just recommended, a plant may become stripped of half its branches.

There are some Dahlias that are apt to produce green, hard centres, which defect is a practical disqualification for exhibition purposes, while it detracts from the decorative beauty of the flowers. Such varieties do best in soil that is both light and moist; and where it is convenient to give them water, as, if they are to produce blooms with perfect centres, they should be encouraged to make a rapid succulent growth. There are some sorts of Dahlias that will throw good blossoms at first, and the succeeding ones come thin; such as these should have an open situation and a heavy soil, in order to produce a slow growth and more perfect blossoms.

It is a great mistake to plant single Dahlias that are only required for cutting purposes in soil as rich as that intended for show varieties. There is a tendency in most single Dahlias to grow rapidly, and heavily manured ground only adds to their vigour. I saw last season some single Dahlias in rich ground, that, though planted 6 feet apart, had grown so close together and so tall, that they had to be tied back with cords, so as to allow anyone to get among them to cut the blooms. Here, then, is one disadvantage from planting single Dahlias in heavily manured ground; another is, that the flowers are large and coarse, instead of medium-sized and refined. R. D.

Leucojum trichophyllum.—In THE GARDEN of May 14 (p. 434) I observe that Mr. Archer-Hind and Mr. Wolley Dod have flowered specimens of *Leucojum trichophyllum*, but some doubt seems to

exist as regards the localities where this plant is found. I obtained it last year near the sea coast of Portugal, from Figueira to the Lake of Obidos; it is also found near Lisbon, as correctly stated in the *Botanical Register*, vol. vii. (pl. 511). It grows in a soil composed of fine sea-sand, mixed with a little fibrous peat. Two varieties have been mentioned by Peninsular botanists—the larger one being known as *grandiflorum*, but, as I find them growing together, I think they are only accidental varieties. Wilkomm gives a very good figure of the *L. trichophyllum* var. *grandiflorum* in a late number of his "Illustrationes Florae Hispanicae." I have endeavoured to introduce this plant into English gardens, as it should flower well in the soil mentioned above and grown in a cool frame in pots. *L. autumnale* (*Acis autumnalis*) grows close to *L. trichophyllum*, and flowers from October till February and even in May.—ALFRED W. TAIT, *Oporto*.

A NEW SNOWDROP.

I BEG to be allowed to protest most strongly against Mr. Wilks' name of *Galanthus globosus* as applied to the large-flowered form of Elwes' Snowdrop. In the first place, the same variety has been illustrated and described in THE GARDEN as long ago as 1881 (Vol. XXV., p. 371) under the name of *G. Elwesi* major, and is not nearly so uncommon in cultivation as Mr. Wilks (p. 115) would lead us to believe. Every cultivator who has dealt in imported roots of *G. Elwesi* must have observed this variety among them. Mr. Smith, of Newry, sent it to me in 1883, and it turned up again in a lot of imported roots from Messrs. Watkins and Simpson, as also in a batch received direct from Smyrna in 1884. As to its twin-flowered habit, all Snowdrops now and then produce two-flowered scapes in an accidental way; but in no single species or variety is this habit a constant one. Seeing that this identical variety is well known in many gardens, and as it has already been illustrated and described in THE GARDEN as *Galanthus Elwesi* major, I venture to suggest that the name *G. globosus* be withdrawn, or at any rate, if retained, that it be used in the third or varietal position, viz., as *G. Elwesi globosus*.—E. W. BURBIDGE.

— I have only two remarks to make on above: 1. My Snowdrop is new. I obtained it as a single bulb in 1880 or 1881 from Smyrna. It is as different from Elwesi or so-called Elwesi major as a long-rooted Radish is from a Turnip-rooted. I have Elwesi major, and I know perfectly well that many modifications of Elwesi appear—so much so that I have ceased to believe in Elwesi major, as I have forms of it intermediate to all stages, and the "major"-ity is often no more than strength of bulb or extra cultivation. 2. Of course, I admit that I may be mistaken, but I submit that so also may be Mr. Elwes and Mr. Burbidge. It is just within the bounds of possibility. And in this instance, notwithstanding the eminence of their names, I slightly incline to believe that they, who have not seen the plant, are more likely to be mistaken than my humble self, who has possessed it for six or seven years and studied its habit and form side by side with almost all the varieties of *Galanthus* known to us gardeners. 3. If whenever anyone, thinking he has something good, or rare, or new, sends you a note of it, and is met by such letters as Mr. Elwes' and Mr. Burbidge's, which, without any question, are not superabounding in courtesy or overflowing with gentleness, the only effect will be that we shall never send you word or note of any kind; and, for my own part, all interest in THE GARDEN would be gone. By all means discuss matters; display the "cons" as clearly as the "pros," but let us neither ridicule the mistakes of a beginner nor abuse the errors of the more experienced, considering that we ourselves were once beginners, and may even yet sometimes be in error.—W. WILKS.

Mortar rubbish for Violets. A friend who grows Violets very well tells me that he finds an application of mortar rubbish to the soil very beneficial. This is put on at planting time and well worked into the top spit, and wherever it is applied

the growth of the plants is much more vigorous. In the case of tenacious soils, I could understand that the mortar rubbish would improve them by rendering them more friable, but my friend's garden, being a light loam, points to the fact that lime is necessary to the welfare of Violets, and it may be that a deficiency of this is the main or only cause why Violets, in some places, are so difficult to grow. Last year I had occasion to remark how well Violets thrive that come from self-sown seeds. This year plants that came up and were allowed to remain undisturbed flowered well. We do not look for effectiveness from the Violet, unless, perhaps, in a cut state; but these plants were so covered with bloom that a bed of them on the grass would have been very attractive. What was remarkable about them was the dwarfness of the foliage which enabled the flowers to display themselves so well. There was an entire absence of that leafiness that distinguishes the growth of Violets in many places. This peculiarity I attribute to no manure having been employed, and to the position being an open one. I feel sure that in time the growing of Violets from seeds will become general. It is so easy to get up a stock in this way, and the thrifty nature of a seedling enables it to live where plants propagated in the usual manner fail.—J. C. B.

THE ORIGIN OF THE EDGED AURICULA.*

IN my paper on the history of the flower at the Primula Conference, 1886, I have presented a series of evidences tending to the conclusion that the florist's Auricula is of pure descent from the wild Auricula of the Alps, the *Primula Auricula* of the botanists. By the same method I have assigned the origin of the alpine Auricula to the supposed hybrid *Primula pubescens*, and this, taken at the valuation of Professor Kerner, carries us back to *P. Auricula* and *P. hirsuta*, its reputed parents. Seeing that we cannot prove every proposition, and must allow opinions to have weight, I feel bound to say that, although my proposals were warmly debated, they were not less warmly accepted by not a few, even of those who in the first instance disputed them. Not to make a catalogue of names, it shall suffice now to say that Sir Joseph Hooker, Mr. J. G. Baker, and the Rev. P. D. Horner concur in my view of the parentage of our two great sections of garden Auriculas. It is no part of my plan on this occasion to enter further into that matter.

I have carried back the history of the edged Auricula to the year 1734, and at that point the edge appears historically to melt into a series of stripes, for anterior to this date stripes were in favour and edges were unheard of. The first edged flower we read of was called "Honour and Glory," as though Fate had emerged from the abstract to the actual in order to have a hand in providing a name for the first representative of a new and glorious race of floral beauties. It is a matter of the highest importance in this connection that while we have in the old books figures of Auriculas, there is no suggestion either in figures or words of an edged Auricula until, in the *Flower Garden Displayed*, by Sir Thomas Moore, we have the characters of Honour and Glory plainly set before us, fixing the date of its origin as certainly not later than 1734. In Parkinson's *Paradise*, p. 237, are figures of Auriculas in which stripes are suggested; but the draughtsmanship is of so rough an order that it would be unsafe to found a critical opinion on any of them. While, however, we may lament that the literary florists of the olden time were not careful of our interests in their floral portraiture, we are not without the aid of the facile pencil in respect of evidence of the kind of flower that gave birth to the edged Auricula. There were men who understood flowers in days when edged Auriculas were unknown, and when possibly the striped Auriculas had not long been invented. It is generally understood that for the Auriculas of the garden we are indebted to the Dutch florists, who made the first beginning in the domestication of the savage of the Alps. And our debt to the Dutch

painters is not less great for representations of the flowers as the Dutch had improved them, and these representations testify to the pure love of Nature by which the Dutchmen of old time were animated both in their horticultural and pictorial arts. The artists of the real Dutch school have never been equalled at any time before or since in the directness of their interpretation of Nature, and the reason of their pre-eminence is seen when we compare contemporary works of other nations, say of the French for example, for the French did follow, as they thought, the wonderful contribution of the Netherlands to the joy of the world. The fact is the Dutch painters of the golden time loved Nature, and lived as near to her as circumstances would allow, but their French disciples, in common with disciples of other nations, loved themselves and lived from Nature, and so failed of true interpretation. The one painted the thing as it was; the other as, in his vain fancy, it ought to be. First in the throng of the Dutchmen who have left on record the characters of the flowers of 200 years since, I will name David de Heem, Abraham Mignon, and Jan Van Huysum. These, in their splendid groups of flowers, show us the Auriculas of the days of Gerard and Parkinson, and there was a golden opportunity for London florists in the last exhibition of Old Masters at the Royal Academy for observing in a picture, by Van Huysum, the characters of the florist's Auricula of his day. I have placed before you a rough sketch of a bunch of flowers as they appear in the centre of that picture. The selfsame flowers, or say flowers of the same type, occur commonly in the groups of Jan Van Huysum; they are usually in trusses of ten or twelve; the pips are of the size and form of show Auriculas of the present day, with bold yellow eyes, a clear paste, and a bold, broad margin marked with stripes of colour radiating from the centre. You will observe in the diagram that Van Huysum's Auriculas had distinct geometrical properties; the edge is wanting, and the body colour is broken into rays, but the proportions are precisely such as modern canons would require were such striped flowers now in demand.

It will be observed, then, as the result of a comparison, that in the progress of time the rays have become consolidated into a belt by the withdrawal of the colour inwards, thus leaving a margin of the green colour, which, as we have agreed in supposing, was the sole colour of the Auricula in the first instance before it became a yellow flower on the Alps. I do not insist on this view, for I am content to deal with facts, and the facts appear to demonstrate that the formation of the edge is a late process, and the facts do emphatically suggest that the edge is formed in accordance with a large plan of Nature much more than by any fancy or fable of man. To put the case another way, I would say that the edged Auricula adds a chapter to the history of evolution much more directly than to the history of fashion in floriculture. We have apparently four colours in a show Auricula; but the paste is but an extension and intensification of the meal, and white and grey edges are of the self-same constitution. The ground colour of the paste is yellow, and the ground colour of the edge is green, and the body colour may be likened to the dark zone on the leaf of a zonal Pelargonium. Van Huysum's flowers show an extension of the yellow to the margin with heavy rays of red overlaid; there is no green traceable; that in the Auricula is a late development, and it has a meaning of some sort apart altogether from our taste and aspirations as florists.

For a moment let me direct your attention to a few collateral facts. In the old books there are no figures or descriptions of edged Carnations. Those of the times of Van Huysum and Gerard were flaked and spotted, and the spotted flowers were called Picotees. The origin of the term has been much debated, but the end of the story is that it came from France, and was applied to a flower distinguished by spots and blotches. The edged Picotee is a late growth, and offers an analogy to the Auricula. The colour has undergone a process of concentration and of segregation, taking an isolated

* Paper read by Mr. Shirley Hibberd at the Horticultural Club on May 10.

position on the very edge of the petals, but always showing a tendency to run inward as a kind of reversion to its original state. The lateness of the origin of the florist Picotee is a matter, as it appears to me, of peculiar biological interest. Again, we have edged and tipped Dahlias, of later origin than edged Carnations, and, like them, fitful in behaviour, the edge tending ever to thrust its colour downward on the face of the florets, and so spoil the flower for the florist's purpose. The lateness of the edged Dahlias accounts for their scarcity and inconstancy; for in truth the Picotee edge is in process of formation, for in these matters Nature does not hurry herself; if man is impatient, she is not, having more time at command than her biped moth that flutters in the flame of its small passions for an hour, and then is seen no more.

It appears that flowers do not begin business with edges, but we cannot say they end with them, because we know not what the end may be. It is of great insignificance that the edge of the Auricula is green; it would perhaps comfort us were it yellow, for then we might consider the colour as an extension from the centre, but the green suggests that the flower is about to change into a leaf, and pass away. We see incipient edges in Pelargoniums, Azaleas, Amaryllis, and other flowers, suggesting that definite edges will be formed in time, but our best examples of flowers that have made up their minds on the matter are the Auriculas, Picotees, Dahlias. These are late developments, and they suggest that the formation of the edge is the result of cultivation, and a proper end to aim at in the selection of seedlings and the framing of exhibition schedules. From *Gardeners' Chronicle*.

Primroses.—"R. G." should obtain seeds of Primroses and sow at once under glass, and thinly in shallow pans. In such case he should have fairly strong plants to dibble out under a north wall by the end of July, and such seedlings would give him fairly large heads of bloom the following spring. Lacking own-saved seed—which is best sown as soon as ripe, because germination is then not only better, but the plants are enabled to grow much stronger for the second spring—it is wisest to sow seed in March under glass, as the seedlings may then be ready to dibble out of doors by the end of May, or even earlier, and thus get them established before the summer drought comes. As to difference in the Welsh and Devon climates, one would think a resident could best give the reason why; but perhaps that of the former is drier, hence the reason why Primroses do not thrive so well there as in Devon. Naturally, a climate which kills double Daisies wholesale could hardly be a very acceptable one, even for hardy Primroses. A. D.

Single white Violets. Permit me to thank the Rev. A. Rawson, Fullbarrow, for his courtesy in forwarding a nice bunch of long-stalked single white Violets. If it proves as free-blooming as the best double white, Comte de Brazza, it will indeed prove a valuable acquisition. The chief faults of our single white Violets heretofore have been their short stems and shy blooming. Most of the older single whites are so short that it is almost impossible to bunch them, and such varieties as the single Czar bloom but sparsely. The Comte de Brazza lost most of its leaves this winter in the open, but this did not greatly lower the quality nor lessen the number of its exquisitely perfect and fragrant blossoms. Neither did the foliage suffer so much as that of Marie Louise. This was so closely cropped as to cut off with it most of the more forward blooms. I have also to thank Mr. Rawson for an admirable bouquet of vari-coloured Primroses, which he grows to admirable perfection in the cool, dripping climate of the Lake district.—D. T. F.

Laced Auriculas.—If "A. D." refers to THE GARDEN (p. 416) he will find that I did not say he introduced them. I was not even aware that they were introduced by Mr. Dean, and therefore could not say so. I understood that they were sent to Chiswick by M. Vilmorin, of Paris; at least, I obtained plants from Chiswick very many years ago, about the time that Mr. Dean exhibited them. If my surmise is not correct, perhaps Mr. Dean can

set the matter right. I would like to allude to another remark by "A. D." He says: "If the Auricula Society continues to exist, I trust it will be able soon to establish a class for half-a-dozen laced alpinines." In answer to this, I may say that they are recognised as alpinines, and may be exhibited in competition in classes K, L, M, N, and O; and, in order to give them a still wider field, there is a special note to the effect that they may also be exhibited in the class for fancies. They have been exhibited in most of the above classes, but they are not refined enough as yet to obtain the higher prizes. "A. D." also complains that I am not correct in designating self-coloured alpinines as self-edged. I believe that I am quite correct in so doing. There is, first, the yellow or cream-coloured centre, and the shaded edge or the self-edge, both of them the margin or edge. J. DOUGLAS.

THE CULTURE OF SWEET VIOLETS.

AS Violets from November to May, or even a month earlier or later, are now expected as a matter of course in many gardens, their careful culture has assumed an importance never dreamt of in those olden times when the traditional Violet border under the shady wall sufficed for generations to supply the wants of good country families. During all the early years of my business I never so much as saw or heard of Violets being propagated, divided, or shifted on to new beds or borders. Old huge-headed Violets made a brave greenery and a cool home for slugs and snails throughout the summer, and mostly threw up a few weakly blooms throughout the spring. But as to bunching Violets in quantity for bouquets, table-decoration, or sale, it was alike impossible and unheard of. A very few tiny bunches to fill the Violet glasses once or twice in the season were all that were expected. As to autumn or early winter Violets, they were wholly unknown. When the so-called tree Violet (the double Russian) was introduced as a pot plant, it was seldom or never forced. Its great merit was to be trained up to a single stem, a tree from 6 inches to a foot or 15 inches high, and then bloomed in the greenhouse or window garden a few weeks earlier than it would have done—did, in fact—in the open air. In passing one lingers a moment to pay a compliment to this. In the depth and fulness of its deep blue colour, and the profusion and fragrance of its blossoms, it is still unrivalled. But the flower-stems were so short as to render its artistic use most tedious and difficult. Anyone would yet confer a favour on Violet cultivators who should mount the old double Russian on to the stout, long flower-stalk of The Czar, Victoria Regina, or odoratissima. By the way, are not these two first descended from the last?

Considerable skill, labour, and space are needed to cultivate Violets in the most successful manner. As to the first, the very keynote of success rests on an annual-renewal of the plants. The temptation is great at times to leave a portion of the stock undisturbed. But it does not answer. Two-year-old plants are less floriferous as well as less hardy than one-year-old, or less. Some may question the first half of this sentence; hardly anyone will demur to the second. The smaller and more compact the plants of Violets the hardier they are. This has been abundantly proved this winter, which has also proved a striking correlation between youthfulness and hardiness; and as to floriferousness, reckoning actual Violets gathered rather than mere shows, the younger ones have the advantage by a long way. A very fine border of two-year-old Marie Louise was left this winter. Through the late autumn and beginning of the winter the ground was covered thickly as a mat with flowers and foliage. The first heavy frost checked the development of the blooms, and the succeeding ones cut leaves and flowers off as if they had been scalded with boiling water. All this while, borders of annual plants close by were but little injured.

The same lesson has been repeated with more or less emphasis many times, so much so, that it may be laid down as an axiom that annual propagation and a new start with single crowns is the true secret of success in the cultivation of sweet Violets. Next in importance to this is the proper time to propagate or

divide Violets. In general terms, so soon as practicable after the plants are out of bloom is the most favourable condition. But as the wholesale propagation of sweet Violets can only be carried on in the open air in most gardens, the matter is somewhat complicated by the state of the weather. To divide Violet plants more or less forced and carefully protected in pits or frames, and plant them out in the teeth of the east wind in April or early in May, is hardly the likeliest course to grow them into model patches of embryo blooms and leaves next October.

It is better to wait than to check the plants at starting. While waiting, those who have the means may divide their Violets and root and start them under glass, transferring them to the open about the beginning or middle of May according to the state of the weather. Plants thus prepared will seldom look behind them if carefully transferred to their growing quarters, and many of them will be in full bloom in September. But the first fortnight in May is a good average time for the propagation of Violets. By this season the best open-border Violets will be sufficiently advanced for division. Frame Violets may be used provided the lights or frames were lifted off as soon as they ceased blooming, and the plants kept clean and healthy by liberal waterings. Skill and labour are also needed in the division and planting of the young Violets. Each good growing centre should be so separated from the mass as to have growing roots attached; the nearer the latter are to the base of the shootlets the better. The plants should also be planted firmly up to the base of the offset. The next considerations affect space or area devoted to the Violets, and this includes site, soil, distance apart, &c. As to site, all have been recommended from direct south to due north, and it must be admitted that success has been achieved on all aspects. Nor is this surprising, considering our infinite variety of seasons and soils. In dry seasons probably the finest Violets might be grown on a north border; in wet ones on a south; and the same might be affirmed of light and heavy soils respectively. But, on the whole, the finest Violets are grown in the open ground without help or hindrance from artificial sites or shelters.

Neither is the Violet very particular about soils, provided they are not too light nor too rich. On the first they are apt to succumb to thrips and spider, or to be destroyed by drought; on the latter they run to an excess of leafage. Common kitchen garden soil should have no manure added for a crop of Violet plants. As to distance apart, that may vary considerably according to the nature of the soil, variety grown, and amount of space at command. To make the most and best of Violets on a limited area, they may be planted quincunx fashion a foot apart; where ground is more plentiful and the soil is richer, in rows 18 inches or 2 feet asunder and a foot or 15 inches from plant to plant in the row. They are mostly grown too close together. By allowing greater space the plants ripen earlier and more thoroughly; every interstice of clear soil becomes in fact a warming-pan, and thus the temperature of the Violet plot is higher where the plants are thin than where they are thick. These clear spaces also favour the other important processes of culture, such as the persistent picking off of the runners and the frequent scarifying of the surface. With a loose surface and a fair depth of garden soil or sound loam Violet plants will seldom need watering. Should, however, long periods of drought set in, the Violets must not be allowed to flag or become flaccid, for the double reason that they have no time to lose, and also inasmuch as severe flagging is almost invariably succeeded by red spider or thrips, and either of these is fatal to perfect Violet culture.

Finally, change the Violet ground every year, for though Violets are not so prone to earth-sickness as Roses and some other flowers, yet they do suffer from it, and hence the importance of giving them fresh growing quarters annually. There is little to add concerning varieties. Odoratissima, Victoria Regina, and The Czar are still the finest singles, and Comte de Brazza (white), Marie Louise, and Neapolitan the finest doubles for general purposes,

There are a good many other names, but I would respectfully invite cultivators to better if they can these six sterling varieties. D. T. F.

The Prophet Flower (*Arnebia echioides*).—Why is this called the Prophet Flower? At the recent exhibition of the Royal Botanic Society a fine pan of this, laden with yellow flowers with black spots, was shown, and it was very effective. It was curious to note that the black spots, which are quite distinct in the young flowers, almost disappear in a few days, leaving only faint marks behind. In this respect it might appropriately be termed the vanishing flower. Mr. W. E. Gumbleton stated that to grow it successfully it should be planted on a dry spot.—R. D.

Single white Auriculas.—I am told this is somewhat plentiful in Scotland. Can any reader of THE GARDEN tell me if it is so? I do not mean the pretty little snow-white *Primula nivea*, which is sometimes termed a white Auricula, and offered as such. I have one that I got from Belgium a few years ago as a double variety, but the flowers are only partly double, scarcely semi-double, and many of them quite single, white, but yet not so white as those of *P. nivea*. Is the Scotch white Auricula similar to this? I have raised a few seedlings from it, but as yet failed to get anything of a similar character. It is a good grower and, on the whole, free of bloom. I name my best double Auriculas, and I call this Bridesmaid.—R. D.

Varieties of Primula Sieboldi.—A goodly number of these were brought forward at the Regent's Park exhibition, and opportunity was afforded for instituting comparisons. One thing is quite certain; we have too many of the character of *P. Sieboldi laciniata*, still one of the best and most distinct. Mrs. Geggie is in much the same way, but paler in colour, and it is slightly lacinated on the edges. Magenta Queen is also very similar. Vivid is smaller and brighter, still of the same character, and also lacinated. Thus we get four that largely resemble each other. A fine and distinct variety is to be found in Brilliant, bright magenta in colour, with stout, flat, circular flowers. Pearl is a good white, stout, and well formed, with the slightest tint of lilac on the reverse of the segments. Lilacina marginata, the bright lilac flowers being margined with a pale colour, is very pretty and distinct; and Charmer, pale rosy lilac, is very good also. Add to these four, laciniata and purpurea, a fine stout, well-formed pale purple variety, and an excellent half-dozen is thereby furnished. They are a sadly neglected, but yet a beautiful and satisfying class of hardy Primulas.—R. D.

SHORT NOTES.—FLOWER.

Prostrate Phloxes.—Some of these were seen to the best advantage at the Regent's Park Exhibition in the form of bold masses in pans. They demonstrated how admirably they are adapted for the summits of rockwork, and indeed in any position suitable for them. The three shown on this occasion were amena, pale rosy pink; Nelsoni, white; and frondosa, pale pink; all very free indeed.—R. D.

Allium Hermetti grandiflorum.—I received last autumn from Messrs. Ant. Roozen & Sons, of Haarlem, some bulbs of this fine variety, which I think is destined to supplant *A. neapolitanum* as a winter-flowering plant. It is more robust and more floriferous; the umbels are, I think, larger and the individual flowers finer; it comes in quite as early if not earlier, and is altogether a very desirable plant.—DELTA.

Allium grandiflorum.—This also I received at the same time. It has large handsome foliage; the flower-stem has already gone up 3 feet and more, but the flowers have not yet opened. If it corresponds to leaves and stem it ought to be something good, but most of the Alliums are disappointing.—DELTA.

Stoncrop in baskets.—This makes a capital carpet plant for hanging baskets of hardy plants. We use the small-leaved *Baunymus*, *Vincas*, or *Periwinkles*, and many other plants for filling baskets, and there is not a more useful plant for surfacing them than the hardy Stoncrops, or Sedums. If put in at the base bottom upwards, it does away with any need for Moss, and soon spreads into a living covering of verdant green, covered in early summer with innumerable heads of yellow flowers.—J. G. H.

Primroses and snarrows.—It is very odd that with swarms of sparrows about this place yet I have been troubled with their attacks on Primroses only once. I have thought the action is not due to want-mess, because that would be crediting the birds with special intelligence and a knowledge

of how to annoy man. I prefer to believe that the act is rather due to a search for moisture when the weather is dry. With thousands of plants blooming profusely almost close to the trees which the birds frequent, still not a bloom has been touched this year. A ditch with plenty of water in it is close by.—A. D.

STOVE AND GREENHOUSE.

T. BAINES.

HERBACEOUS CALCEOLARIAS.

A BATCH of these plants in full flower at the present time is very useful for conservatory decoration, succeeding the Cinerarias, and coming in just before the bulk of the Pelargoniums. We do not see these Calceolarias generally grown well in private places, as oftentimes they have to share positions in houses with other subjects quite unsuited to them. Treated in this way they generally fall a prey to greenfly, which is their greatest enemy. To have them in bloom by the first of the month the sowing of the seed is generally deferred too long; thus sufficient time for the plants to grow to a good size before they are required is not allowed. The flowers in a cut state do not last a long time, but the plants when used for the decoration of the dwelling-house and placed so that they receive a fair amount of light are very showy and most interesting, as the colours vary much when seed is procured from a good strain. The habit of growth, compared to what it was a few years ago, is also so much improved by careful selection, as to render this plant much more desirable in every way. To have the plants in full flower by the end of April or early in May, the seed should be sown thinly in large pans about the first week in June, using a compost of half peat and leaf mould, adding to this a plentiful supply of silver sand, the whole passed through a fine sieve. By sowing the seed thinly the seedlings do not grow up weakly, a circumstance to be avoided, as a sturdy growth at the start makes all the difference between success and failure in the future. Many causes of failure in obtaining a sufficient number of plants might be traced to allowing the soil to become dry during the germination of the seed. If the soil is moist no water will be required for a time, but when water is required it should be allowed to soak through the bottom of the pan until the whole mass is thoroughly moist, care being taken not to wash the seed off the surface. Thoroughly drain the pan by filling it three parts full of crocks, and over these place a layer of rough leaves, pressing the soil firmly in the pan and maintaining an even surface to within half an inch of the rim. Upon this surface sow the seed thinly, gently pressing it down, and covering the whole with white sand, which favours the quick germination of the seed and induces a quick rooting of the plants. Over the surface of the pan place a square of glass, covering the same with Moss, which assists in retaining the moisture in the pan, or a piece of slate, which preserves the moisture better than glass, may be placed over the top of the pan. Place the pan in a cold frame behind a north wall. The seed will quickly germinate, and as soon as the seedlings appear above the soil admit air by slightly tilting the glass on one side and removing the shading, and if slates have been used, substitute glass. As growth progresses remove the glass entirely, and give a little air to the frame. When the seedlings are large enough to handle, transplant them carefully into other pans about 1 inch apart, using the same kind of soil with the addition of some loam, sifting all fine as before. Return them to the frame, and keep close for a few days until the roots have taken to the new soil. Gently dew the plants overhead with tepid water, and admit air gradually as growth proceeds.

When the leaves touch each other the plants will be ready for their first shift into pots $2\frac{1}{2}$ inches in diameter, using rather more loam and not sifting the soil so fine; return the plants when potted to the frame. By keeping the frame under a north wall during the summer months shading is dispensed with—an important item in the culture of these plants, as it often

happens that when the frame is placed in a sunny position sufficient moisture is not maintained about the plants, and they fall a prey to green fly, which, if not quickly eradicated, soon cripples the plants to such an extent that they hardly ever retain that vigour which is essential to success. During the summer months a damp atmosphere within the frame must be preserved, the plants standing upon a thick bed of coal ashes. As soon as the roots reach the sides of the pots, and before they are in the least pot-bound, shift them to a larger size, according to the size of the plants, until they are in their flowering pots. Some of these may be 10 inches across if large specimens are required, while they will so vary in size that some will remain in 6-inch pots, in which they are very useful for decoration in various ways. After the first shift the soil may have more turfy loam and a small quantity of horse manure partly decomposed added to the previous mixture, and leaving out some of the peat. For the final potting, which usually takes place in January when the plants are in their winter quarters, the compost should be as follows: One part good fibrous loam of a light character, one part leaf-mould and partly decomposed horse manure, half a part of peat, some finely ground bones, some charcoal and sand, using all in a rough state, and potting lightly. Do not place the plants deeper in the pots than previously, as sometimes, owing to an excess of moisture, they damp off at the collars.

About the middle of September, or sooner should the weather be cold and dull, the plants will be benefited by a change of quarters, viz., by placing them where they will obtain more light and a little sun. Still resort to shading them if the sun be very strong, and admit air freely to the plants by tilting the lights, gently syringing them overhead every evening. Retain them in this position as far into the month of October as is safe, covering the frames each night in case of an early frost injuring them. When the plants are not considered safe in the frame, or at all liable to lose their foliage by damp, remove them to a cool house where the temperature is kept so that frost does no harm. Beyond this no fire-heat will be required, beyond an occasional warming of the pipes, to dispel damp during foggy or damp weather. Great care should be exercised in watering them. Never water unless it is required, and, if possible, always use soft or rain water in a tepid state. When the plants are thoroughly established in their flowering pots, some stimulant will be an advantage. Nothing is better than occasional doses—say, every second time water is required—of weak liquid manure, that from sheep or cow manure being the best. Early in March the flower-stems will begin to throw up above the foliage; these will require some support, which is best done by placing to each a small stake. By training the flower-stems in an outward direction, those growing from the middle of the plant will have room to develop thoroughly, and thus prolong the display and preserve the colours in their proper character. A light shading should be placed over the glass, as the richer colours quickly lose their brilliancy under a hot sun during the months of April and May.

If the plants are allowed to become pot-bound or dry at the roots, they seldom regain their natural vigour. When there are any signs of greenfly on the leaves, smoke the plants with Tobacco in the evening, and again in the morning, as the second application will effectually destroy any that may be left alive from the first dose. After this, give the plants a good washing with the syringe, which will leave all sweet and clean. E. M.

Agathæa cælestis (Blue Daisy).—Now that Daisy-like flowers are so popular, this plant is far more extensively grown than was the case some years ago. It is a most accommodating subject, and may be had in bloom throughout the year with but the simplest treatment. The pretty pale blue star-like flowers are borne in great profusion on long wiry stalks, so that when cut they may be employed in many arrangements. Not only is it useful for cutting from, but it may be grown into neat

little bushes, and is then valuable for greenhouse decoration. To succeed with this *Agathaea* and thus obtain a supply of bloom throughout the winter, cuttings must be struck in the spring or early summer, and, after the first shift, plunged outdoors. They must be pinched back frequently, and, as the pots get full of roots, shifted into larger ones, so that by the end of the summer, if they have been carefully attended to, the plants of this *Agathaea* will be in the shape of neat little bushes full of flower-buds. In the warm end of a greenhouse, or in a structure kept at an intermediate temperature, they will flower throughout the winter, and some of our plants that had been flowering till the end of March were slightly shortened back and given a good dressing with Clay's Fertiliser, the consequence being that they broke strongly into growth, and are again thickly studded with bloom.—H. P.

RESTING EUCHARIS AMAZONICA.

I do not in the least question the accuracy of the description of the fine pots of *Eucharis* at Gunnersbury Park, but unless "R. D." (p. 410) has either been wrongly informed or has blundered sadly, Mr. Roberts will not long be able to point to such a valuable stock of this popular flower. This is "R. D.'s" extraordinary version of the Gunnersbury treatment:—

Mr. Roberts states that the secret of growing *Eucharis* is that when a young leaf comes up, a flower-stem will be sure to follow, and as soon as the young leaves appear the plants should be dried off and the flower-stem comes up.

This may be correct enough as far as the leaf forming prior to the flower-stem appearing, and in the case of well-grown bulbs as many as three or more flower-stems may be obtained in one year. By all means grow them in a high temperature, with plenty of room and shade, and if not often potted they must also have abundance of water and frequent supplies of soot water or other liquid manure. To dry them off, however, "as soon as the young leaves appear," is simply suicidal. It ought to have occurred to him that the leaves must largely contribute to the strengthening of the bulbs as well as the formation of the flower-stems, and instead, therefore, of crippling these, every attempt should be made to properly develop them.

The withholding water from well-established plants for a short time, or say giving only sufficient for about three weeks or a month, to prevent flagging, may safely be practised by experienced cultivators, flower-stems showing in abundance directly after they are started again. A slightly reduced temperature for about the same time, accompanied with rather less water at the roots, followed by re-introduction to strong heat, will excite the plants into flowering equally as well. In either case this rest ought not to be enforced before the last batch of leaves is fully matured, or anything but satisfactory results would be the consequence. In the majority of gardens in this country the *Eucharis* are not strongly established in their pots, and I hold that unless they are root-bound, or at any rate approaching that state, nothing in the shape of drying off ought to be attempted, and that all advice to the contrary given by inexperienced persons is calculated to do much harm. All the time there is fresh soil for the roots to occupy they are active, and they ought to be encouraged to remain so. Dry them off and there is the almost certainty of the bulk of them perishing, and the mite or other insects gaining the ascendancy. Subjecting weakly plants to a temperature ranging from 60° to 50° is also an unwise proceeding, as this also seriously checks root action. After all I am not convinced that it is even advisable to dry off a lot of strong plants unless a large quantity of bloom is required at a given time. We have a small house devoted principally to *Eucharis*, and are very rarely without a few flowers, while at intervals a fairly large quantity is open at one time, yet there is no drying off. The very variability of a climate seems capable of affording all the excitement needed to induce them to flower any time during the spring, summer, and autumn months. A spell of dull cold weather followed by the opposite will frequently cause all to flower that are in a fit state to do so. The flower-stems of various bul-

bous-rooted plants are frequently formed in an embryo state many weeks before they show themselves, and a little excitement is all that is needed to bring them forward. This I have repeatedly discovered, and the drying off such plants as *Eucharises*, *Crinums*, *Vallotas*, and *Amaryllis* is therefore an uncalled-for proceeding, and is more often than not responsible for what is attributed to the attack of mites and other insects. I repeat other insects, for mites are not the only tiny insects to be found in unhealthy *Eucharis* and *Vallota* bulbs.

W. I.

LARGE-LEAVED PANICUM.

(PANICUM Plicatum.)

In this genus are numerous large, and in some cases gigantic Grasses. They are widely distributed throughout the tropical and sub-tropical portions of the globe, but many are robust enough to stand our climate during the summer. The variety, *P. plicatum*, of which the annexed woodcut gives a good idea, is, like many others in the genus, very useful for mixing among flowering plants in the conservatory or for cutting from; although it may be planted out during the summer months, it will be found to do best under cultivation in pots. To succeed

The large-leaved Panicum (*Panicum plicatum*).

with it, it must be grown in heat, more especially during the winter months. As it is of a free rooting character it requires to be grown in good sandy loam to allow of the water, with which it must be liberally supplied, to pass away freely. There is a variety with variegated foliage called *niveo-vittatum*. Both may be increased by seed and division of the roots. The plants, however, raised from seed are the best.

Mitraria coccinea.—Among greenhouse shrubs remarkable for the beauty of their blossoms and at the same time but rarely met with in gardens, mention may be made of this South American plant, which is now in full bloom. It is a native of Chili, and, consequently, is nearly hardy, but to be seen at its best, must be treated as a greenhouse plant. It forms a much-branched bush, in general characters not unlike a slender-habited *Fuchsia*; while the bright red urn-shaped blossoms are borne in great profusion. It succeeds best where shaded from the full rays of the sun, and when grown in an open compost consisting of fibrous loam, peat, and sand. As the roots are by no means vigorous, thorough drainage must be ensured, especially if it be planted out, for this *Mitraria* is a good pillar

plant where subjects not more than 6 feet high are required. It may also be grown as a pot specimen and turned outside during the summer, but for that a shady place should be chosen as the foliage is apt to become yellow if exposed. Cuttings of it strike root readily enough during the growing season if the young shoots are taken and treated as *Fuchsias* and similar subjects. They will take longer than a *Fuchsia* to strike, but, provided good cuttings are obtained, success will in most cases follow.—H. P.

A PROFITABLE HOUSE.

OCCASIONALLY we meet individuals who maintain that it is almost impossible to grow fruit and flowers well together, and now and then we read as much in the gardening periodicals. I, too, much prefer to have houses as far as possible devoted to one or two subjects, but having in bygone times been obliged to adopt more makeshift practices, am well aware how profitably a small forcing house can be utilised on the mixed system. In quite a small span-roofed house I have grown good and continuous crops of Tomatoes, Cucumbers, and Melons, with a few Ferns and fine-foliated plants underneath, while the next compartment was shared by Grapes, Tomatoes, and Stephanotis. The Cucumbers were planted in a central pit, the Melons were disposed along the south front of the house, being grown in large pots plunged in a hotbed of leaves, while the Tomatoes were planted in boxes and occupied the ends of the house. The Vines were planted in a front pit, and being well attended to at the roots soon took possession of the soil and perfected heavy crops of comparatively large bunches. The white varieties coloured well, but the black sorts, including Hamburgs and Alicantes, were more remarkable for their flavour than for finish. They were only fruited once, then thrown away, and their places at once occupied with late Tomatoes; these in their turn having to make way for more Vines grown in pots in another house. The Stephanotis was grown in a tub and completely covered the north side of the house, the Vines being given the southern half of the roof. Tomatoes occupied one end, as in the other compartment. There was no staging under the Stephanotis, but on the concrete floor were grown Ferns, Pandanus, Crotons, Dracenas, and other plants. Everything succeeded surprisingly well, but all needed and received close attention, each being kept in its place and as clean as possible. I never had a better supply of Stephanotis flowers, nor did the little front air given by night and plenty of top air by day when the Grapes were colouring seriously check its growth. Some of the Tomatoes were exhibited successfully at the London show, and I have never been able to surpass them since. Smooth, round sorts being principally grown, these are invariably more liable to crack before they are ripe, but by cutting directly they commence to colour, cracking is anticipated and the fruit will ripen quite as well on a warm shelf, the precaution being taken to shade them from bright sunshine. The temperature of a Cucumber house, and the moist atmosphere also maintained, suit Melons equally as well as Cucumbers, and should the former crack when ripening they may be cut and ripened off the plant.

In this neighbourhood a gentleman who takes a very active interest in his garden grows a greater variety of plants in one house than I have ever attempted, and his success is noteworthy and ought to encourage others similarly situated to persevere in the direction I shall endeavour to plainly point out. The house under notice is span-roofed, and about 16 feet wide. It runs from north to south, and adjoins a greenhouse. Every ray of sunshine appears to reach it, and in addition it is well heated. There is a central brick pit and side stages. The end of the house is entirely covered with a plant of *Stephanotis floribunda*, the roots being confined to a good sized pot. In one corner stands a strong pot plant of *Bougainvillea glabra*, and this, only very lightly trained, flowers abundantly for several months. In the opposite corner a pot plant of *Allamanda Hendersoni* is grown, and this also flowers early and late. A *Dipladenia amabilis* occupies the corner next the greenhouse, but its treat-

ment not being quite so well understood, it almost failed. On the staging along the west side of the house were grown a number of Tomatoes in pots, these being trained up the roof a length of about 3 feet. The true Dwarf Orangefield is the variety preferred, and rightly so, it being of really dwarf habit, is very prolific, no difficulty being experienced in setting a heavy crop; the fruit ripen quickly and are of good flavour. It is neither a large nor showy variety, but connoisseurs consider it superior to all in point of quality. On the opposite, or east side, early Cucumbers are grown, these also being in pots and not trained more than 5 feet up the roof. Telegraph is the sort grown, the fruit being available in March, and up to the time when they are plentiful in frames, when they are cleared out and their places occupied by late Melons. For the latter the staging is removed, and small pits are formed over the pipes with loose bricks. Planted early in June, in good loamy soil, these Melons grow rapidly, and yield many good fruit early in August or during September. The varieties preferred for this position are Hero of Lockinge and Blenheim Orange; but for the central pit, which is planted with Melons early in April, such sorts as Longleaf Perfection and Easton Castle are preferred. Four plants are put out in nothing but rich loam, this being warmed by bottom-heat pipes. All side shoots are rubbed off till the roof trellis is reached, when they are allowed to spread at will, fruit being set as soon as possible, and at intervals, so as to secure a good succession. They receive plenty of water at the roots and occasional light surfacings of manure. I have seen several very fine Melons cut from this house; they are frequently too large, in fact, but the quality is always good.

When Cucumbers, Tomatoes, Allamandas, and Bougainvilleas are grown in pots, they require to be closely looked after, a few hours' neglect almost ruining them. There ought always to be a tank of water in the house, and this convenient supply largely contributes to the success of the undertaking. The Cucumbers should be lightly cropped and top-dressed with turfy loam occasionally, and then, if otherwise well attended to, overhead syringings and slight shading included, they will remain in a healthy bearing state for many weeks. Tomatoes in pots, which are also much benefited by top-dressings, require plenty of water and liquid manure, and will not be injured in any way by overhead syringings. Whatever number of main stems are laid in, all should have the side shoots kept closely rubbed out, the foliage being quite sufficient to swell the stems and the fruit. Moreover, they require plenty of light, and if all the side shoots are allowed to grow, these would soon smother each other as well as the clusters of flowers. What stopping or thinning out is necessary in the case of Melons should be done early, as if the superfluous growths are allowed to remain, so as to necessitate the use of a knife, the wounds may not heal readily. A little powdered quicklime or Portland cement will dry a wound or any canker in the stem, and thereby save the life of a plant. Stephanotis, with their roots confined in a pot, require plenty of water and weak liquid manure, especially when growing and flowering freely, and these, if well attended to, will yield surprising quantities of fine trusses. Allamandas must be thinly trained, and as at each flowering point they form two or three side shoots, these should be reduced to one or two at the most, and these being laid in will duly form other flower-spikes. On no account should these spikes be cut, as they continue to lengthen and flower all through the season. The plants require abundance of water and liquid manure, and without it they soon become unsightly and useless. Bougainvilleas and Allamandas soon take possession of a top-dressing of turfy loam and old cow manure, and the former also must have plenty of water and liquid manure, as well as frequent overhead syringings—red spider if allowed to gain a foothold soon spoiling the foliage. Dryness at the roots will also cause them to shed nearly all their leaves. Dipladenias should have very different treatment. They require a rough peaty compost—no loam being used—plenty of drainage, and com-

paratively small pots. Water must be given very cautiously, an overdose quickly spoiling the plants. Such varieties as Brearleyana, amabilis, and Williamsi are most beautiful, but the more easily grown boliviensis is also very pretty, and can be had in bloom nearly all the year round. The latter roots more freely, and therefore requires more water, and when the pots are well filled with roots a top-dressing of fibrous peat and a little loam and old cow manure will materially assist them.

During the winter the house just alluded to is filled with Begonia semperflorans, Knowsleyana, Ingrami, and erecta multiflora, semi-double zonal Pelargoniums, a few Tea Roses, and a variety of Ferns and fine-foliaged plants. Altogether it is most probable no plant or fruit house in the country gives much better returns for the outlay, and it is a source of never-ending pleasure to the proprietor.

W. I. M.

Helleborus viridis as a market plant.—

This is one of the least showy of the Lenten Roses, but it has so much beauty of form, that it would be worth a place in gardens even if it gave no flowers at all. The deep green shining elegantly divided foliage, so hardy that such winters as the past one make but a feeble impression on it, render it no mean ornament to the outdoor garden during the winter months. As regards general appearance, it quite equals many tender fine-foliaged plants grown for decoration, and I have often wondered that it should never have been taken in hand by market growers and florists. I was looking the other day at some two-year-old plants, compact specimens about a foot high with thick spreading crowns of foliage, and I thought how attractive they would look in 6-inch pots, and how likely such healthy little specimens would be to find favour in Covent Garden. This Helleborus may be grown as a market plant, but I have never seen it employed in that way. Were I growing fine-leaved plants for decoration I should certainly give Helleborus viridis a trial.—J. C. B.

Acradenia.—A genus containing a solitary species, belonging to the Order Rutaceae, the chief distinguishing characters of which are calyx and corolla in fives; stamens free, not joined together, and quite smooth; the anthers also smooth and destitute of any appendage; the ovaries close together and enveloped in a dense woolly covering, and bearing on each summit a small gland which gives rise to its name. It is a robust-growing plant, producing an abundance of white flowers arranged in terminal, many-flowered corymbs. The soil best adapted for this plant is a mixture of peat, loam, and sand in the proportion of one of the latter to two parts each of the former. A. Franklinie, the plant in question, is named after the late Lady Franklin, and, apart from the interest which its name inspires, is a valuable addition to the greenhouse. Stems and branches terete and rough; leaves opposite, trifoliate; leaflets lanceolate, somewhat coarsely toothed on the edges, glandular and deep green on the upper side, paler below, the whole plant diffusing an aromatic perfume when rubbed; peduncles terminal, forming many-flowered heads of snow white blooms, which are produced during the early spring months. A large plant of it may now be seen in bloom planted out in the temperate house at Kew. Native of the district around Macquarie Harbour, Tasmania.—G.

SHORT NOTES.—STOVE AND GREENHOUSE.

Azalea Miss Jarrett.—This was shown by Mr. H. James, of Lower Norwood, at the recent exhibition of the Royal Botanic Society as a new variety. The flowers are of large size, stout, and fringed on the edges, with slight markings of lively green on the inner segments. It is a very free and fine variety, but whether an English seedling or a Continental introduction was not stated.—R. D.

Azalea mollis in the open.—In some parts of Wales these are just now in great beauty in the open air. They are charming flowers, and are a grand addition to Whitsunide blossoms. The plants are in no way shy in growth; they are bushy and compact in habit, and the profusion of their orange, straw, salmon, rose, and other coloured blossoms attract the attention and command the admiration of all who see them. They merit far more attention in the open than they have yet received.—CAMBRIAN.

Asparagus plumosus nanus.—The Maiden-hair Fern which for so many years has held the foremost rank in supplying foliage for bouquets and other forms of floral decoration appears at length to have met with a formidable rival. The Asparagus plumosus will undoubtedly supplant it as soon as a sufficient quantity of it is forthcoming. At present the demand is in excess of the supply in Covent Garden, and doubtless will be so for some time to come. There is no doubt here an opportunity for anyone with sufficient capital to purchase largely, holding and propagating their stock for a year or two to make a good hit. The sudden brisk demand for this plant will, of course, send up the price, so that the buying of any quantity will necessitate considerable outlay. The speculation would, however, be sure to be a paying one. I am informed that nearly all of this Asparagus that is brought into Covent Garden is bespoken. Those market growers who cultivate the Maiden-hair Fern largely will be wise if they gradually substitute the Asparagus for it.—J. C. B.

SEASONABLE WORK IN PLANT HOUSES.

SINGLE PRIMULAS.—Plants that have been raised from seed sown some time since will now be large enough for pricking off. To grow Primulas well they must be kept moving freely from the time the seed vegetates until they come into flower, as if the plants, especially during the early stages of growth, get into a stagnant condition they will not afterwards make up the lost ground. One of the most frequent causes through which these plants suffer is by being allowed to remain too long in the seed pan, where their roots get so matted and entangled that they cannot be separated without breakage, and their leaves become drawn through want of room. The usual way of proceeding is to move the little plants singly into small pots, in which they remain until large enough for transferring to those in which they are intended to flower; but a better method is to prick them off in shallow boxes, allowing enough room for them to remain in these without the leaves overlapping each other until the plants are large enough to be transferred to the pots in which they are to flower. Treated in this manner, much of the attention in watering which such things when in little pots require is saved, and they will gain much more size and strength in a given time than when confined to pots, whilst the facilities which the boxes give in keeping the plants raised up to the glass are much in their favour. See that the soil is sufficiently light and open in texture to admit of the plants being taken up without breakage of the roots when the time comes for finally potting off. Leaf-mould, rotten manure, and fresh loam passed through a fine sieve, with a little sand added, are the right materials with which to fill the boxes. Abundance of light, free admission of air, with a thin shade when the sun is bright, are the necessary conditions for securing the stout, stocky growth so essential in a well-grown Primula. A little more seed may now be sown, the plants from which will come in useful for flowering after the earliest set is over.

SEMI-DOUBLE PRIMULAS.—The semi-double-flowered varieties of Primula are deserving of general cultivation. Seed of these may now be obtained in the various different shades and colours that in recent times have appeared. These half double kinds come sufficiently true to their respective colours to be relied on. The points in their favour are that they are better growers than the double sorts, whilst their flowers are much more enduring, especially in a cut state, than the single varieties. Their cultivation is the same in every respect as that of the single kinds.

DOUBLE PRIMULAS.—These may be propagated at any time during the spring and summer when side shoots in right condition are to be had. If there is any deficiency of stock, more should be put in now. There is less danger of the cuttings suffering through damping at this season than earlier on. A little warmth with shade and a moderately confined, but not too close, atmosphere are necessary to get them to root. Some of the later forms that

have appeared have larger flowers than the older kinds, but for general usefulness when well managed it is a question whether the old double white and its slightly different newer variety are yet beaten. The size the plants attain under good treatment and the profusion of flowers they produce are unequalled. Where white flowers are much in demand for bouquets, they supply material during the early months of the year when there are not many things to choose from. Where large specimens are required strong established plants should be moved into bigger pots, being careful afterwards to keep them where they will have plenty of light, as when the plants get large, unless the growth is made under conditions that will ensure its being strong and robust, the stems are more liable to suffer from damp in autumn and winter than smaller examples are.

LILIES.—Old bulbs of *L. auratum* that have got well established and have bloomed several seasons are much more to be depended on than such as are newly imported, or that have been grown for a single season, as it not unusually happens that they grow and flower the first summer and then die; whereas, with fair treatment, when once the bulbs have got over the severe ordeal inseparable from their long voyage and the long time during which they are out of the soil, they go on thriving and increasing in numbers. This species of Lily submits fairly well to forcing, but though this is sometimes done, I look on it as a mistake. During the latter part of spring the number of plants that flower naturally is such that there is no necessity for hurrying on the Lily in question, and when a healthy, thriving stock of it is obtained, it is better policy to treat it in a way that will keep the plants strong and vigorous, rather than flower them out of season. As has before been pointed out when speaking of *L. auratum*, there is much difference in the time that the bulbs flower. This peculiarity should be noted, and the roots treated accordingly, having the earliest to come in first, with later ones to follow. The continued healthy condition of this and other Lilies, when subject to pot culture, is much dependent on the way they are treated during the time they are making growth; they are naturally light-loving plants that do not like being located where their stems and leaves become drawn and weak. From this time, when the danger from spring frost is past, they are best out in the open air with the pots plunged in coal ashes, and their stems safely secured from rough winds, and for this reason a fairly sheltered position should be chosen for them. For late summer and autumn flowering there are no Lilies equal to the different varieties of *L. speciosum*. These should be treated in the same way as *L. auratum* through the summer. Amongst the host of Lilies now in cultivation many thrive best and are only fit for growing in the open ground, whilst some, like *L. auratum*, *L. longiflorum*, and *L. speciosum*, succeed better in pots. By selecting a few of those that are most distinct in the character of their flowers a succession may be had in bloom from the first months of the year up to autumn, beginning with the earliest and best forcer, *L. Harrisii*, to be followed by its near ally, *L. eximium*, which is the best of the older forms of *L. longiflorum*, as it produces double the number of flowers. By forcing a portion of the stock of this sort, and having others to come on in cool quarters, with the common old *L. candidum*, also grown cool, an almost unbroken succession may be had until the first of the auratum flower. Neither should the stately *L. giganteum* be omitted, for though, in common with many other Lilies, it will succeed in the open ground in some localities, and under some conditions of soil, &c., it is still a grand object in a pot. So grown I have seen it far better in every way than I have ever met with it out of doors. As pot plants for conservatory decoration these Lilies can scarcely be over-rated, whilst the flowers of the smaller-flowered sorts are very useful in cut-flower arrangements. Plants of the earlier-flowering kinds, or such as have been brought on slowly to succeed them, must be well cared for, giving them plenty of light and attending to their wants in the matter of water, as unless strict atten-

tion is given to these points until the leaves and stems die down, it is useless to expect their continuing in a healthy, vigorous state.

BRUGMANSIAS.—For covering the back wall of a large cool conservatory, or, still better, trained against the glass at one end of a house of this character, *Brugmansias* are amongst the most effective of all plants. To do justice to them, if on a back wall, the structure must not be a dark one, for if deficient in light, only the tops of the plants will flower freely. Vigorous-habited plants, as the larger growing kinds naturally are, require more root room than things that attain less size, though much may be done to keep up the requisite strength by renewing the surface soil of the border annually. When grown against the glazed end of a roomy house the plants are seen to most advantage, as the light they get in such a position causes them to flower more freely. Grown in this way, or as more usually seen in the form of bushy headed standards or pyramids, they will now be in active growth, and should be regularly supplied with manure water, particularly in the case of old specimens that have their roots confined in pots or tubs. By having a few extra plants a succession of flowers may be obtained, as if a portion is now turned outdoors in a sheltered place they will bloom after those that are kept under glass are over. In all cases keep the syringe going freely to preserve the foliage from insects. I have found none to equal *B. Knightii* and *B. suaveolens*.

STOVE. PANCERATIUMS. Of the various species of *Paneratium* in cultivation, *P. fragrans* may be set down as the most generally useful. Where fragrant flowers are required for bouquets it is not easily equalled, or for arranging in large vases where the spikes are used entire they are equally effective. The time of blooming varies considerably with the amount of heat the plants are subjected to, but in most cases they will now be in full growth. They are light-loving plants, and, provided means are taken to keep the leaves from getting injured by the sun's direct rays acting on them, the plants increase the fastest and bloom the most freely when kept in a light position. Where at all underpotted, manure water should be given once every ten days or a fortnight, being careful not to apply it too strong. *Paneratium* and all the kinds of their near allies, the *Hymenocallis*, that I have tried will, if the spikes are cut before the flowers expand, open freely in water, attaining a size only a little inferior to that which they reach when left on the plant. When the flowers have to be sent any distance it is much better to thus cut them before they open, as then they are not disfigured by the pollen getting scattered on them. T. B.

KITCHEN GARDEN.

W. WILDSMITH.

THE RUBBISH HEAP.

THE above words have not a very refined sound, but to a gardener they are full of meaning, as designating a place of the utmost importance in assisting him to keep the entire garden trim and neat. Of course, much that is wheeled from the garden has sooner or later to be wheeled back, yet this apparent double labour is in every sense of the word most profitable, as in the first place it ensures neatness, for every scrap of dead and decaying matter is, or should be, regularly taken away; and, secondly, that same material is again returned with interest to the ground in the form of manure of the highest value. Our manufacture of it—manure—is continuously going on, and the ingredients are as varied as they are numerous. There is grit, the sweepings of walks; there is vegetable matter, the old stumps and leaves from Cabbage and Broccoli; also Potato haulm, weeds, and green vegetables not required for use; then there are soil and opening material, in the form of refuse from the potting sheds; and, lastly, there are all the scraps from the

prunings of fruit trees, the trimmings of Ivy and hedges—these last we burn, and after reserving the best of the ashes for use separately, the remainder is thrown together with the other ingredients, and twice during the winter the entire mass is turned over, and a little salt, soot, and freshly slaked lime are added as the work goes on. These have a destructive effect on insect life, and the heating settles any seeds of weeds there may be. After this second turning the heap is allowed to stand for another month or six weeks, when it is ready for application to any description of vegetable crop. Peas, Celery, and Globe Artichokes seem to revel in it, and on our sandy soil it is most excellent for Potatoes. The refuse of our garden is thus returned to the soil, and our rubbish heap again cleared for another year's campaign. I wish that the refuse of the furnaces was as easily got rid of, for this grows in spite of our new walk and road-making, the foundations of which we always form with clinkers and ashes for the double reason of reducing the heap and preventing the growth of weeds and formation of Moss that invariably happen when walks are made entirely of gravel.

VEGETABLE GROWING.

WHAT with the extension of houses in gardens and the cutting up of work into sections, such as Orchid, plant, fruit, and decorative departments, there seems to be no great anxiety on the part of young men to acquire a good knowledge of hardy plants, or of vegetable culture. The ordinary opinion seems to be that anyone can grow vegetables, but I think there are few head gardeners who do not find one of their most valuable garden allies in a reliable and practical kitchen garden foreman. Generally, too, the kitchen garden work, because it is rough and laborious, falls to the lot of the ordinary garden labourer, and if observant and intelligent he can as a rule far more easily obtain a situation at an increase of wages than can young men whose time is almost entirely spent in the houses. Whilst there are vast numbers of gardens in which vegetables are principally grown, those in which houses predominate are limited in number, and good single-handed gardeners may often find better wages and more places to select from than house-trained young men can whose aspirations are higher. There is some reason for belief that we are approaching a time when high-class vegetable culture will be made one of the most important of garden elements. Hitherto plants and fruits have enjoyed the chief attention of the gardener under glass. Dwarf Beans in houses and frames and early Potatoes in frames are the principal, but still not remarkable exceptions. What is needed is such a knowledge of vegetable culture, both in houses and frames, that an ample supply of the best description shall be produced literally all the year round, but, of course, chiefly during the winter and spring months when vegetables are scarce and far from being tender out of doors. If it be pleaded that warmer climates give us all we need during our blank seasons for the mere trouble of purchasing it, there is great force in the observation that no imported vegetables can ever give us that freshness and flavour which go to make good home-grown products. The vast sums of money spent by those having a love for Orchids would serve to supply a table with vegetables which at present may be regarded almost as luxuries. Cheap glass houses and frames with moderate heating power would produce wonders in the way of choice vegetables, and, being fresh and sweet, would also be more valued than the best which Covent Garden could furnish. Where gardening is a pounds, shillings, and pence question, it may be asserted that vegetable culture under glass would not pay; but some things cannot well be appraised at a money value, amongst which is the pleasure experienced in partaking and enjoying the produce of one's own garden. The tendency of the age in most things is of a utilitarian cha-

racter, and in gardening that tendency is asserting itself. We have but to note the prominence given of late years to Tomato culture under glass to realise how popular such products may be made. What is done so largely for Tomatoes may presently be done for some other things now grown as best they can be out in the open, and therefore it behoves young gardeners to give close attention to vegetable culture in all its varied forms and aspects.

A. D.

KITCHEN GARDEN NOTES.

THINNING OUT.—Favoured by a copious rainfall, we have been able to thin out all crops that were ready for that operation; Parsnips are thinned out to from 10 inches to 12 inches apart. The second sowing of Turnips has also had the same attention; distance apart about 6 inches. Summer Spinach was mainly thinned as required for use; now that the crop is finally thinned, the plants are from 6 inches to 9 inches apart. This crop quickly runs to seed, and on that account many do not thin out the seedlings at all; this was once our plan, but finding that increased space considerably lengthened its season of perfection, we now always thin it out the same as we do winter Spinach. Early Horn and Early Nantes Carrots that were sown on a warm sheltered border early in February are nearly ready for use; they were sown thinly to obviate the necessity of thinning out the seedlings, but those who have not exercised this precaution would do well to thin out to about 3 inches apart. Owing to pressure of work, we have occasionally omitted to prick out (prior to final planting) Cauliflowers, early Broccoli, and Coleworts, but in lieu of this have drawn out the smallest to give the remainder more room, and the plan has answered very well, and once again it has been done to each of the above. At the same time there is no doubt but that the best way is to prick out the plants, and if time and labour can be spared it should be done.

ASPARAGUS.—At last daily supplies are possible. As a rule we discontinue cutting as soon as Peas are ready, but if this be done this year we shall have had an open-air Asparagus season of about a month's duration. Of course, the rule will this season be disregarded, and in prospect thereof, we have given the plot a dressing of guano, and the recent heavy rain will at once make it of service to the present season's supply. Salt and soot have been scattered over a newly planted plot. We use the two together, and both are excellent manures for the crop, as the salt keeps weeds in check, and by mixing soot with it there is no need to use it in such quantity as will make the surface soil adhesive or pasty, and therefore liable to get hard on the surface in dry weather. Hoing will, of course, remedy this, but it is just as well to prevent that operation being so frequently necessary by being more moderate in the use of salt.

VEGETABLE MARROWS.—The demand made on us for this vegetable is very limited—indeed, is almost nil so long as Peas are to be had in quantity; hence our aim is quantity at the end of summer rather than early supplies. We have now put out the plants on open parts of our soil-yard, the ridges or beds being composed of scrapings from roads, edgings of walks, and the siftings of soil from the potting-shed. Bottom-heat is out of the question, and, in fact, in this part of the country (Hants) unnecessary. The plants are strong, were in 5-inch pots, and have been well hardened; still, it was deemed necessary to afford shelter to the plants by affixing round them Yew branches, and as matters turned out it was well this was done, for the morning following the eve of planting the thermometer fell to 29°, or 3° of frost, and they were not injured.

POTATOES.—As all but our latest crops are up, it has lately been an anxious time with us in regard to their protection from frost. They have been kept earthed up, and as yet no injury has befallen them. Were it not as a protector from frost, earthing up on our light soil would be entirely discontinued, solely for the reason that the Potato might get immediate, and therefore the fullest amount of benefit from the rainfall, which for our light soil is seldom

too copious—indeed, I may say never, except when the murrain prevails; then, of course, we would prefer that the crop had none at all. Such an arrangement is, however, beyond our power, and the next best plan is (provided the tubers are anything like nearing maturity) to lift and store them at once. We are now digging fairly good tubers from frames, or rather that were in frames, but these structures being wanted for other purposes, a skeleton framework made with stout rods was fixed round the beds, and on these, when needed, was placed coverings of canvas, mats, or felting. The first supply we grew in pots, shifting them from one house to another as exigencies of space and the necessary temperature to keep them growing demanded. The beds from which we are now having supplies will presently be utilised for the growing of Capsicums, Solanum capsicastrum, Bouvardias, rooting the runners of Violets preparatory to planting them in frames at the end of summer, and for raising from seeds many varieties of herbaceous flowering plants.

CAULIFLOWERS.—Broccoli seem likely to hold out longer than usual, and present prospects are favourable to a continuous supply till early, frame-wintered Cauliflowers are ready, of which some few already show signs of hearting; and to such we have given a good soaking of clear manure water. Another small planting has been made of Early Dwarf Erfart and a first batch of Autumn Giant; other small plantings of the latter variety will be made once a fortnight up to the end of July. After rain, whilst the ground was wet, the drills in which all that have been planted this spring were filled in to the ordinary ground level, and no further earthing up will be necessary, nor artificial watering either, provided mulching is done before the ground gets dry.

GENERAL WORK.—To look over Asparagus daily, cutting such heads as are ready, and tie up tight to keep the heads straight. If stood in an upright form in shallow pans of water and in a cool place—light or dark—it will keep in perfect condition for quite a week. Sow Radishes fortnightly, Mustard and Cress about every ten days. Cut back seeding herbs, plant out any that have been raised from seed. Thin out Salsify, Scorzonera, and Dandelion to from 6 inches to 9 inches apart. Also thin out Lettuces, stake seeding Onions, keep seed stems off Rhubarb, Seakale, and Horseradish; stake Peas and Runner Beans.

W. W.

Hardy Broccoli.—I do not credit the statement that Mr. Gilbert can find "any number of cottagers" who can grow Broccoli or anything else better than "half the gardeners in the country," no more than I believe that his Cabbage Broccoli is a Broccoli. It has no more Broccoli about it than any other Cabbage has when bursting with its seed-stalk. If I am wrong, I ask him to produce one sample in proof of it from the Land's End to John-o-Groat's. I have never seen the Broccoli in Chou de Bughley, nor met anyone who did; but I do know of some who have bought seed of it in the expectation that it was what it is described by Mr. Gilbert, and been ruefully disappointed. Produce me one head in any way differing from any other good Cabbage at the same stage, and I will acknowledge my error. I do not care one straw for the independent testimony Mr. Gilbert speaks of. Show me the Broccoli. It has been too long belauded in THE GARDEN on that head, and it is time someone asked for some sort of proof. I would suggest Mr. Gilbert exhibits both at some show. The fact of the matter is, a Cabbage cannot produce a Broccoli head; it is impossible. Broccoli and Cabbage flowers are the same; but the Broccoli or Cauliflower "head" is only produced in some members of the Brassica tribe that never close up in Cabbage form, and under no other circumstances.

—J. S. W.

SHORT NOTES.—KITCHEN.

Rhubarb Ruby.—Forced Rhubarb, or when grown in a cellar in the dark, comes to table when cooked of a nice red or pink colour, and is far more enticing to the appetite than when it is green in colour, as it generally is when used

from the open ground. There is a sort called Ruby, which when cooked is of a beautiful ruby colour, and has also a much better flavour than the sorts usually grown. It does not grow so strong as Victoria or Linnaeus, and requires good ground to grow it well. I think if Ruby was better known it would be grown very extensively for its nice colour when cooked, and I would advise those who have not grown it to get it. I feel sure that they will be pleased with it when it comes to table.—R. LLOYD, Brookwood.

Failure of early Potatoes.—Some early Potatoes which were planted in my garden in the second week of March are not yet above ground. The sets were home-grown, from some plants of Veitch's Ashleaf, purchased in 1886. A deep fall of snow followed by severe frost came on just after the planting; that weather, however, did not last a fortnight. We have, as everybody knows, a great rainfall here in Lochaber, but spring is our driest season; these Potatoes have had but very little rain. The ground was newly trenched and left rough. The Potatoes were planted on the system universal here, namely, raw manure is laid in the bottom of the drills, and the sets placed upon it and then covered up. The drills in this instance were about 6 inches deep. If any of your correspondents can point out any fault in the system pursued that would prevent the plants from growing properly, I should feel grateful. I should mention that when examined last week the tubers when taken up were not killed.—E. C. M. Fort William.

GARDEN FLORA.

PLATE 598.

NEW HYBRID MONTBRETLE.*

THE three beautiful hybrids most accurately portrayed on the accompanying plate were raised by the well-known French nurseryman, Victor Lemoine, of Nancy, and distributed by him in the spring of 1886. They bloomed abundantly in my garden during the summer and autumn of that year, and though they suffered a good deal during the long winter both from damp and frost, they are now shooting up strongly, and

Montbretia crocosmiiflora, showing habit of plant.

will, I hope, bloom again this summer. M. Lemoine is this year sending out, besides a fine form of one of the parents of these hybrids under the name of M. Pottsi grandiflora, two more new hybrids named Le Phare and Solfatare, of which I hope to be able to give a description in THE GARDEN in the autumn when they bloom with me. They both seem to be of quite as free-growing a nature as their brethren here figured, and will, it may be hoped, present some pleasing varieties of shade and colour. These plants were much admired by all who saw them in my

* Drawn by Miss Travers in Mr. Gumbleton's garden, at Belgrove, Queenstown, Ireland, August, 1886, and printed by G. Severyns.

NEW HYBRID FORMS OF MONTBRETIA CROCOSMÆFLORA

garden last autumn, and were a most marked improvement, both in size of bloom and brilliancy of colouring, on any of the hybrid forms that had preceded them. W. E. GUMBLETON.

FRUIT GARDEN.

W. COLEMAN.

PACKING GRAPES.

Good Grapes, like other choice fruits, are often injured by indifferent packing for long journeys, the injury, if not to the berries, certainly to the bloom, in nine cases out of ten, being the outcome of temerity. Because Grapes, once valuable, are, or should be, beautifully coated with a delicate bloom, many people are almost afraid of touching them, and yet a moment's reflection should tell them that friction in transit is the main cause of all the mischief. Although for many years hundreds, if not thousands, of tons have been sent to all parts of the kingdom and the Continent, the methods of packing still are legion. When I was a youth, Henderson, the veteran, packing for transit by coach and rail, placed about 20 lb. in a square box, as tightly as one bunch would rest against another; then prior to putting on the lid he drew strings across to keep the shoulders up. Noted Scotch growers, packing for very long journeys, I am informed, fold each bunch tightly in a sheet of soft paper; place these packages, like pounds of Tea, in flat boxes, and wedge up with paper shavings. Growers about London, who never lose sight of their Grapes from the time they are cut until they are delivered by hand or spring vans, have a decided advantage over long-distance men, especially when the latter have to prepare for transfer from one railway company to another. The first use baskets of various shapes and sizes, but generally round, for the reception of the bunches; shoulders upwards and outwards, points in the centre. These bunches pass direct from the hand to the basket, when a tie to each stalk keeps them in place, whilst the tendency to wedge downwards prevents friction. A thin covering of paper to keep out dust finishes the operation, and the Grapes arrive without spot or blemish. The latter, myself included, adopt the plan followed by the veteran, and approved of by the leading Covent Garden fruiterers—less the troublesome process of stringing up the shoulders. The boxes I use for Hamburgs are 24 in. long, 14 in. wide, and 7 in., sometimes 8 in. deep, the depth being regulated by the size of the bunches. Fresh, sweet Moss, prepared as for Peaches, is used for padding the bottom, then two or three thicknesses of soft paper complete the preparation. Moss being used for tightening the Grapes after they are put into the box, it is necessary to allow at least one half of each sheet of paper to hang over the outside and ends of the box to prevent it from working in amongst the berries during the process. The box is then weighed, taken to the vinery, and tilted on its end at an angle of 45°. Cutting is then commenced, the first bunch being laid or rather set, shoulders well up in the extreme left hand corner; another goes into the opposite corner, and the third in the centre of the end forms the wedge. Tightness to prevent friction being the main object, bunches large or small are selected, and in this way the packing, row after row, goes on until the box is nearly full; it is then raised to a much sharper angle and allowed to descend with a sharp shock upon the table to carry the bunches and berries still closer together. More bunches then are introduced until a piece the size of a shoulder cannot be got in and the box is ready for weigh-

ing. The weight taken, the half sheets of paper are turned up, and being three-ply thick they will stand a little drawing inwards with the left hand to form a cavity for the introduction of Moss between the side of the box and the paper with the right. In this way Moss is firmly, but gently pressed in until all the berries brought suddenly together without friction are as tight as paving stones. When no more Moss can be introduced, these half sheets of paper are turned back to keep it down and form the commencement as it were of an arch, which prevents the shoulders from touching the lid, although the box in transit may be turned upside down. A sheet of tissue paper is then strained over the top; the lid, in one piece, is put on, lightly nailed and stoutly corded. Good Grapes should never be entrusted to delivery companies, neither need they be addressed "Till called for" or to be met, and the consignee is advised beforehand.

ORNAMENTAL FRUIT TREES.

I NEVER recollect a more beautiful show of fruit blossom of all kinds, for though unusually late, owing to the protracted winter and severe frosts in spring, yet the bloom does not appear to have suffered in the least, and we may reasonably hope for a good and fruitful season. The question of employing useful fruit-bearing trees in the pleasure grounds as ornamental subjects crops up from time to time, but the examples one meets with of trees actually growing and doing good service in the double capacity of useful and ornamental trees have hitherto been more the results of accident than design. From the great changes that have occurred in gardening matters during the last twenty years we may at least hope that the usefulness of any given tree will be no bar in future to its being honoured with the best place that can be given it in the ornamental grounds. Old customs and prejudices are rapidly giving place to new ideas. Trees that are not either useful or ornamental will be rooted up. It would be difficult to say which fruit tree is the most beautiful; all have their admirers. I have long since decided that the Apple bloom is the prettiest. Although this is not the time for planting Apple trees, let us note which is the most beautiful when in bloom, and again at the gathering in of the fruit we may note which makes the most striking effect on the tree. I think that trees that grow entirely unpruned are the most showy when in bloom, for although I have some bushes, pyramids, and espaliers lovely masses of bloom, they cannot equal the long, pendulous branches of the naturally grown standards. Lord Sutfield and all the Codlin type are very beautiful, and the Scarlet Goff is brilliant in spring and autumn, a good cooking Apple, but hard and sour as a Crab. For a fine tree, Elenheim Orange is difficult to beat, and a good Apple for all purposes. Deux Ans is one of the great orchard favourites in Hampshire, and makes noble trees; while for keeping up a succession of late bloom, Court Penda Plat is the latest, and certainly one of the best of Apples. It will be June before it is in bloom.

Gosport.

J. GROOM.

Late-keeping Apples.—"A. D." says (p. 438, May 14) that the problem of keeping Apples through a long winter is solved. He does not appear to have tasted the Apples—the one thing most needful. Such Apples may be kept and *seem* to be good when they have wholly lost their brisk, pleasant flavour and their wholesome and refreshing qualities! Our Apple-growing needs healthy change, but this way of showing autumn and early winter Apples with nothing but the good coloured skin to recommend them is only throwing dust in our eyes.—R.

Tomatoes.—The only way to gauge the success of any method of culture is to measure it. If Mr. Gilbert claims his restrictive method of growing Tomatoes as the best, let him test in that way and publish the results. If his method is the best, I will adopt it the day after I am made sure of it. Up to now (May 20) I have gathered fully 40 lbs. of

the common red Tomato, most of which has fetched 2s. and 1s. 6d. per pound to the trade, while foreign ones were selling retail at 1s. and 1s. 6d. per pound, and at the present date I have hanging about fully swelled, coloured or colouring, at least 200 lbs. more on sixty-one plants struck last October, and anyone can see them and judge who likes. That is nearly 1 lbs. of fruit to the plant, and it takes no account of quantities of small fruit newly set or just swelling. What are Mr. Gilbert's weights and number of plants, and how far on are his January-sown plants? Mine are all entering into full bearing, and some ripe fruits have been gathered. I would have gathered much more, but lately the fruit has ripened slowly owing to the dull weather, and we do not use much fire-heat.—J. S. W.

THE BEST TIME TO PLANT STRAWBERRIES.

SOME useful remarks on this subject recently appeared in THE GARDEN (p. 399). They were in favour of spring rather than autumnal planting, and, as is natural, they made the worst of the latter and the best of the former. No harm was done, for no doubt spring planting has its advantages, and it is equally certain that capital Strawberries are grown by both methods. My object now, however, is to point out a system of summer planting which is practised by Mr. Allan, of Gunton, and others most successfully, and to which, so far as I am aware, no objection can be urged. Its basis consists in growing the main crop of Onions a little more than double the usual width and intercropping the Onions with Strawberries so soon as rooted runners can be obtained either from forced plants or not.

None of the usual objections urged against autumnal planting can be urged against this, for, in the first place, it is really summer rather than autumn planting, if a sharp outlook is kept for the earliest runners. The soil of the Onion quarter is also proverbial for its hardness and solidity. This favours the rapid rooting and vigorous growth of the Strawberry plants.

As the latter grow into size the Onions ripen and are harvested, leaving the Strawberries in full possession, which furnishes them with abundance of space. The removal of the Onions and the scarification of the ground where they grow gives a useful fillip to the Strawberries. Should ground be scarce, as it mostly is in these hard times, a row of Lettuce or Endive may be run along on the late site of the Onions, and will yield nice cuttings of useful greens in the autumn or winter. Thus the same ground will have produced three good crops within the year, and the cultivator may almost be said to have got his Onions for nothing, so far as the ground is concerned. Though he does not grow so many Onions as by the usual and more close-cropping system in general use, yet the Onions are finer, so that there is less loss of gross weight than might be supposed, while the larger Onions, if sold, command higher prices in the market. As to the Strawberry plants, they almost equal, occasionally excel before the end of the season, those runners planted in the spring in the usual way. The Lettuces or Endive are another clear gain.

In cases where there may be any difficulty in obtaining the current year's runners sufficiently early, last year's runners pricked out into nursery beds may be drawn upon in the usual way. These, however, should not be planted till June, lest they should outgrow the Onions and lower the quality or lessen the bulk of this chief main crop. Strawberries grown thus yield enormous crops of first-rate fruit the following season, and may either be dug in after their first crop or allowed to yield a second, as considered most profitable. Beyond the first year there is nothing special in the culture or cropping. Some have thought that the residue of the Onion crop might affect the flavour of the Strawberries, but it does not, even when the above system is so modified as to grow fruiting runners abreast with the Onion crop. This may readily be done by planting the interstices with Strawberry runners from the nursery beds soon after the Onions are fairly up. Nice pickings of fine fruit of excellent flavour may be obtained thus the first season

without any sensible diminution of the main crop of Strawberries the succeeding season.

HORTUS.

STORE ROOMS FOR APPLES.

IN reply to "A. D." in THE GARDEN, May 11 (p. 437), respecting the mode of keeping the Apples recently exhibited by us, we have pleasure in giving the following description of our store. The room is built on the ground level, the outer walls of 9-inch brickwork. Inside this, wooden quartering is placed and lined with match boarding, facing the inside, and allowing a circulation of air between the woodwork and the walls. A light set of rafters is then placed overhead, lined underneath or inside with match-boarding. On this is laid about a foot thickness of straw thatching, and over this another set of rafters covered with tiles. A window is placed at one end with a double set of casements, one for the outer and one for the inner walls, a small ventilator being placed above it with movable shutters, a shutter also being hung over the window inside to exclude the light. It also has two doors, one inside the other. Internally it is fitted up with shelves 2 feet wide of thin close boards, which are placed 1 foot apart from the floor to the roof, the floor being paved and covered with cement. Previous to storing the fruit the shelves are covered with a thin layer of clean wheat straw. The fruit is then placed on the shelves, one, two, or three layers thick, a thin piece of board placed between each variety, and a label with the name in front. We do not cover the fruit with straw, and the less they are disturbed after this the better. Of course, they require looking over from time to time to remove any defective fruits.

As to temperature, on several occasions during the past winter it fell as low as 2° or 3° below freezing. But this with a low outside temperature does not damage the fruit in the least, provided that the room is kept close and the inside temperature is allowed to rise gradually with that of the outside. There is not the least difficulty in providing good sound Apples through the spring if the following essential points are attended to: first, to select the right varieties; secondly, to see that the fruit is thoroughly matured before gathering; and thirdly, to provide a suitable store in which to keep it.

To store Apples in bulk for marketing purposes, of course a much simpler structure than the one described above would answer all practical purposes, and those who have Apples of suitable varieties for keeping would find that a little outlay in this direction would pay them well. Our English growers are gradually learning the lesson, long ago learnt by our American cousins, as to the great importance of selecting the right varieties to fulfil certain definite purposes, and planting these and these only. With a little care in these respects our English growers would leave no room for Americans to supply our markets.

J. CHEAL AND SONS.

Crawley.

Preparing Strawberries for forcing.—I think I shall be in touch with most gardeners when I say my favourite plants for forcing have one crown only, well developed, and plump. Numbers of our forcing Strawberries are potted too early. Here I wish to describe the varieties which cannot be potted too early, and also the varieties which may. For our first earlies we grow La Grosse Sucrée, which has no inclination to split its crown. Our second batch is Sir Charles Napier, which, potted at the same time as La Grosse Sucrée, will grow into half-a-dozen crowns, which I think a bad omen. British Queen is also one which requires early potting; by this, I mean from the 20th of July to the 1st of August, and what I look upon as late potting is from the 15th to the 25th of August. A great favourite variety with me (to ripen in February) is Laxton's King of the Earlies. Potted late in 4½-inch pots, they bear quite charming little fruit, and the flavour is excellent. For the latest of all Strawberries I look upon Oxonian as best, either for forcing, or for growing out of doors. It is large

in size and magnificent in colour; in fact, a model of what a Strawberry should be, but it is not a quick grower. My plants of this variety for pot work next year are late runners, now potted and under glass in 3-inch pots; when they get well established we pot them in their fruiting pots, and use 8-inch pots. They make splendid specimens, keep their crowns entire, and so are in the best condition for forcing purposes.—R. GILBERT.

RED SPIDER.

ON one point only should I decline to agree with Mr. Coleman, when writing on the above subject in THE GARDEN, May 14 (p. 436), and that is in the use of sulphur to eradicate red spider. I have a firm conviction that the remedy in this case is even worse than the disease, and that the sulphur fumes are even more injurious to plant than to insect life. As in the case of many forms of aphides, red spider has its favourite haunting grounds. One may hardly find a trace of it out of doors in some places, whilst in others, during a very hot dry summer the hedgerows will be nearly skeletonised by the pest; and under these circumstances the gardener must be very diligent to keep out and indoor fruits free from its ravages. "How do you manage to keep your Peaches so free from spider?" I asked once in a garden that I was looking over, and the reply was, "an occasional slight syringing is quite enough to keep them clean." I should like to say the same; it is not, however, slight syringings, but very careful winter cleaning, repeated scalding of pits in the case of the renewal of Melons, Cucumbers, Beans, &c., and heavy and persistent drenchings of foliage in the case of in and outdoor Peaches that are required in our case to keep the pest in check. With abundance of spider on outdoor hardy vegetation (apart from all garden considerations) through the summer, old walls that bear the impressions of nearly 200 years' mauling, and three-fourths of the houses blue-heated, I may claim to have a tough battle to fight with spider, and may also claim to have invariably kept the upper hand of it. In the case of pits used for growing Melons, Cucumbers, and French Beans, a thorough scalding is given before starting, every nook and crevice being well saturated with boiling water. I never find the insect troublesome in the pit devoted to Cucumbers all through the growing season, the state of humidity essential to the well-being of these not being relished by the spider; but as soon as Melons and Beans are kept a little on the dry side it makes its appearance, and the only remedy is to push fruits and vegetables rapidly along and clear them out as soon as possible and again have recourse to unlimited supplies of boiling water before renewal. In the case of Peaches and Nectarines both in and outdoors, as soon as the first signs of spider are seen, the trees get a drenching with the mixture already referred to in THE GARDEN (November 27, 1886, page 195), taking care to attack on all sides, that every particle of foliage may get a thorough wetting. Outdoor Peaches had their first dose early in April, for on looking over the trees before putting on the netting I found the spider on the move, and consequently took prompt measures to check its increase. Strawberries (which we have to grow in vineries) get a good dipping before they are taken inside, and if spider show itself on them before the fruit is over, they are removed to some cold frames or pits. In the case of Vines, we act almost entirely on the principle that prevention is better than cure; all woodwork and glass being thoroughly washed, and walls, floors, &c., scalded before the Vines are started, and the temperature during the spring months is kept rather on the low side, it being far better in the case of blue-heated structures to be content with a decline of 5° on very cold nights than to maintain the usual figures with a dry scorching heat. Such are the remedial measures and precautions adopted in our case to keep spider in check, and it will be seen that sulphur is not included in the list. If anyone can conclusively prove to me that foliage that has been badly attacked with spider shall, after the application of the sulphur to the pipes, be quite free from the pest, and itself quite uninjured by the

sulphur fumes, I will be a convert to this particular remedy, but not until then. E. BURRELL.

SUPERIOR HARDINESS OF YOUNG STRAWBERRY PLANTS.

THIS has been strikingly illustrated in an accidental manner during the long and trying winter hardly yet ended. While I write a collection of about a dozen sorts of Strawberries, planted out on a piece of ground for trial, is before me. After testing and proving them a press of other work prevented the runners being trimmed off in the usual manner; hence they have passed through the winter with runners and old plants intact. On looking at them recently the runners were so fresh and strong, and the old plants amongst them so much crippled, as well as those in the general quarters, that it was determined to leave the runners intact, and now this mixture of old and young plants promises to be the most fruitful piece of Strawberries in the garden. "Slovenly culture!" some of your most fastidious critics will cry. Just so; but this is not the point; neither does the hopeless jumble of sorts matter much in this case, as the sorts are kept true in another place. But the fact of those young plants passing through the winter without the loss of a leaf, while all the older ones were defoliated, is most suggestive.

Neither does this one sure and certain proof of the superior hardiness of young Strawberry plants stand alone, for it so happened last autumn that certain changes in the movements of the family led to several hundreds of young plants prepared in pots for forcing to being planted out in the open ground. These, like the runners in the collection, have also escaped with their leaves intact, and promise to be the second best crop to the runners. Can it be that the superior hardiness of runners over old plants was known to our fathers, and was one of the causes of their at one time growing Strawberries almost wholly in beds, especially in the north of England and Scotland? One thing is certain, that in many of the most fruitful examples of the bed system of Strawberry-growing the runners largely supplemented the produce of the older plants. The plants in the crowded beds also tended to keep each other warm. And as to produce from a given area, I have never yet seen my first experience exceeded in weight from beds of the Grove End Scarlet, Caroline, and Keen's Seedling. HORTUS.

Grubs on Raspberries.—The largest grower of Raspberries about here has all his canes infested with a small insect, which you will find snugly deposited inside the stem of young bud sent herewith. I would be glad to hear what it is, also any remedy for its destruction.—ANON, *Hirksworth*.

* * * The Raspberry shoots you sent are infested with the caterpillars of a small moth (the Raspberry shoot borer, *Lampronia rubicella*), which belongs to that destructive family, the Tineide. The caterpillars will soon be turning into chrysalides, from which the moths will emerge in the course of next month. From the eggs which they will lay another generation of caterpillars will be hatched. To prevent this cut off all the affected shoots at once and burn them. When pruning the canes cut them well back and remove any rubbish round them, particularly dead leaves, stumps of canes, &c., for the caterpillars are supposed to pass the winter in such places. G. S. S.

SHORT NOTES.—FRUIT.

Monstera deliciosa.—We have received from Mr. Fish a fruit of *Monstera deliciosa*. It was perfectly ripe and of good flavour.

Tomatoes.—Would some of your readers kindly state what may be considered the average weight of crop per plant from the large red Tomato? The plants have now three sets of bloom, and are in perfect health, and trained on the single stem system.—G. A. S.

Pears in May.—So few of the late Pears are worth cultivation, that to find a really good, juicy, well flavoured, and eatable Pear fit for the table in the middle of May is worth recording. Such is Belle des Abès, a Pear of the first quality, and averaging about three to the pound. I obtained my trees from the nurseries of F. Jamin, Bourg-la-Reine, near Paris. The fruit are excellent, from espalier

trees, and this variety should be more extensively cultivated. —W. NEW FOS, *Hills, N. Corkon-Croat.*

Apple Norfolk Beaufin.—Mr. Crook, The Gardens, Farnborough Grange, sends us some very beautiful samples of this fine late-keeping Apple. It is generally of a dull bronzy hue, but the samples sent were of a beautiful bright red colour. He also sent Sturmer Pippin and Alfriston in good condition.

SEASONABLE WORK AMONG FRUITS.

FIGS.

A CHANGE to milder, if not brighter weather will now favour the admission of more air by day, and a liberal chink on the pieces of the ventilators through the night. Fire-heat to a certain extent will still be necessary, as colour and flavour until we have much warmer nights cannot be secured without it, neither can the second crop of fruit, now a good size, be prevented from dropping under sudden fluctuations. If the latter had set thickly they should be well thinned before the trees feel the strain of the crop; and the better to increase their size, good warm diluted liquid may be supplied to the roots at every watering. Top-dressing too, especially to trees in pots and contracted borders, will also be found a great help, as not only will it prevent the surface roots from drying out, but, being well charged with ammonia, it will produce conditions favourable to the progress of the second and the finishing of the remainder of the first. The most difficult operation just now is syringing, for much as the swelling fruit and foliage enjoy copious drenchings, the ripening fruit colours and attains its best flavour; and, moreover, keeps and travels best when direct syringing is discontinued. The trees, however, being subject to spider, all stems and available parts of the foliage must be freely syringed at least once a day, and a general bath may always be given after picking in a little closer than usual. Upon this give-and-take principle, the two crops may be managed, and spider, although the season has been harsh and bad, may be prevented from spreading. Next, as to stopping, thinning of the shoots and training, the mode of procedure will depend greatly upon the size of the trees and the space at command. Pot trees, be they pyramids or bushes, must be more or less pinched or stopped to keep them within bounds, but, with the exception of an extra cross-shoot, growths of ordinary strength should not be pinched more than twice, and may not require it more than once, as every growth so checked must make another, and that must have time to ripen, otherwise it will be of little use for next year's forcing. When trees are trained on trellises and all shoots that have reached the extremities are well thinned out at the winter pruning, the extension system of laying in suits them best, as they keep showing so long as they are growing, and although the late shows are ribbed off before they are larger than nuts, their period of ripening can be prolonged or reduced at pleasure. In all cases side growths and weak spray should be removed, as good Figs cannot be expected where sun and air are excluded.

Succession houses.—The trees in these will take any reasonable amount of good food both in the way of mulching and stimulating liquid, and the syringe may be regularly plied twice a day. If not already thinned, such kinds as the fruitful Brown Turkey should be taken in hand at once, and freely divested of superfluous and imperfect fruits. When thinning all other fruits we usually, I may say always, take away the smallest and leave the largest, but in this, as in some other respects, the Fig requires distinct treatment, for if we leave all of one uniform size we have a glut and a gap; therefore, so long as they are perfect in form and well placed, some large and some small ones should be left on every shoot. Here, again, pinching should not be indulged in to any great extent, as it is much the best to secure one full crop and a trellis full of ripe points and trust to cases or walls for the autumn supply. In times past many people were too fond of pinching, especially in late houses; now they secure better crops and keep the trees in better order by pruning back every alternate shoot to a dormant bud and laying in young growths for succession.

Young stock.—Spring-struck cuttings must be pinched as soon as they have made 9 inches to 12 inches of growth, more or less to suit the mode of training. This first pinching will induce side breaks, and when they get into free growth a moderate shift may be given to the plants. It is possible to grow a cutting into a fruiting tree in one year, but unless urgently wanted a little more time is an advantage, as firm, short-jointed, well-ripened plants, established in 6-inch or 7-inch pots and with three or four breaks, make the best foundations. These, if shaken out in March, re-potted and placed in bottom heat, will now be fit for the final shift into their fruiting pots, which should not be large, as ripe wood and roots are of more importance than size, especially when young bushes are wanted for early forcing.

STRAWBERRIES.

If not already done, this troublesome family should now be ejected from Peach houses and vineries, and placed in snug pits or frames to finish out the season. This clearance made, a thorough cleansing of all the shelves with strong soap and water must follow, and a wash of quicklime and sulphur will make the walls sweet and clean for the season. In many places the late vinery in which the leafage is late is used for May Strawberries, and dearly they are paid for, as many houses of Lady Downe's suffer through spider attacking the leaders and working gradually, I may say rapidly, downwards at a time when the syringe cannot be laid on freely. Strawberries, of course, must be grown, but light pits are the most suitable places for them. If these were built upon the span with shelves facing north and south the fruit might not only be grown, but retarded for a considerable time, and the flavour would be greatly improved.

Late hatches in various stages from flowering to swelling will now take an abundance of water, and, where the fruit is set, liberal syringing. The fruit upon these should be well thinned and tied to, or supported by small sticks to keep it well up to the sun and air; otherwise, although well coloured, it will be found acid, as fire-heat, we hope, may now be dispensed with. If the plants are plunged in large masses they must have plenty of room for the full development of their foliage; but instead of moving, and so disturbing the roots of all, their wants may be met by taking out and replugging every alternate row. Should mildew put in an appearance, the plants may be well syringed on mild evenings with clear sulphur water, which must always be used in a clarified state. Some varieties are very subject to mildew, and I have heard people say they have given up growing this or the other, apparently overlooking the fact that nine out of ten cases of mildew amongst pot plants originate in the water-stinted open quarters. When mildew gets into a garden, a fresh start on deeply trenched, heavily manured ground with young runners from a distance should always be made, but on no account should runners from mildewed beds be pegged down for forcing.

Future work.—If any of the forced plants are intended for planting out, they should be in the ground this month. A good preparation is more than half the battle. The balls should be thoroughly moist, divested of all corks, and slightly reduced, to set the coiled roots at liberty. Firm planting, heavy mulching, and copious watering will complete the operation. Last year's runners put out in August for propagating from should be divested of all their flowers and well watered to encourage vigorous stock. It is yet early to commence preparations, but time flies; therefore advantage should be taken of wet days and other favourable opportunities for getting a supply of clean pots and corks ready for use. The compost, too, may be prepared and thrown up in a heap in the open air, where a good covering of fresh stable litter will improve and ripen it, especially if bone-dust or other slow fertilisers are introduced.

CHERRIES.

Houses in which Cherries are ripe may now be kept cool and airy, moderately moist, and certainly safe from birds. I have found cast-off pilchard

nets the cheapest and best material for this purpose, as they keep out small as well as large birds, and whilst admitting light and air they form an excellent shade when cast over the roof. Cherries will keep for a long time in a dry, cool house, always provided the roots are moist and well mulched, but their season can be considerably prolonged by light shading that will break the rays of the sun without excluding the air.

Later sorts, including the best Bigarreans, may still be syringed and liberally supplied with water. They must not, however, be exposed to checks, especially at the roots, as giving and withholding water is one of the most common causes of cracking. A light, not over-rich mulch will keep the roots properly moist against a daily increasing summer temperature and plenty of air will prevent moisture from hanging about the fruit. To colour Bigarreans and other large-leaved sorts properly, they must have plenty of light as well as air; therefore, the better to secure this important point, thin winter training should be insisted upon, and all useless summer spray must be kept thoroughly under hand. Insects should be completely destroyed before the Cherries approach the ripening stage; the most troublesome are black and green-fly, which cannot well be killed without the aid of Tobacco or a decoction of Quassia, and as either of these is liable to give the fruit an unpleasant flavour it is unnecessary to say this work must not be left until the eleventh hour.

PLUMS.

These and Cherries so far have succeeded very well together, but the ripening of the earliest of the latter renders it necessary to separate the two or moderate their treatment. Isolation, however, is better than moderation, as Plums may be freely syringed for some time to come, and it is a difficult matter to syringe one part of a house without charging the whole of the atmosphere with moisture, which, as all Cherry forcers know, sometimes works serious mischief in a few hours. The treatment of early forced Plums in no way differs from that of other orchard house trees. Cribbed and confined to pots, they are entirely dependent upon the hand of man for their daily wants; therefore, being free livers they must have the run of good top-dressing, fresh and often, and liquid at every watering. The syringe, too, may be freely applied; indeed a thorough flooding of the fruit will do less harm than a flush of spray, but the water must be soft or free from lime. Forced Plums will stand a strong heat after they are stoned, but they do not respond; therefore to have them ripe early they must be started early, with an abundance of air throughout their season of growth.

Late houses containing Golden Drop, Jefferson's, Gages, and others have had an excellent time for the setting of the fruit. As some of these, especially the first, set in immense clusters, they should be freely thinned with a pair of Grape scissors, a few as a matter of course being left to compensate for dropping. If the trees are planted out and trained upon trellises, the spray must be constantly pinched to prevent waste, and at the same time to let in light and air, all leaders and necessary shoots being regularly tied in the same as Peaches. Mulching of some kind will be necessary, but its quality must be regulated by the age of the trees and the crops they are carrying. Old trees will stand a very liberal dressing of good rotten manure, not once, but two or three times in the course of the growing season. Young ones, on the other hand, although bearing equally good crops, might push a growth which would barely ripen. To these it is just possible the best of all non-conducting coverings will be found in stable litter or a portion of an exhausted Mushroom bed, anything in fact that will absorb and give off moisture without producing a gross habit of growth.

PEARS.

Although the cultivation of Pears under glass dates back to the erection of the earliest orchard houses, it is to be regretted that this mode of growing the very choice varieties has not made more progress. Worked on the Quince stock, they are

worth growing if only for their bloom; but when it is borne in mind that these snowy pyramids in due course produce fruit of the largest size and of the finest quality, surely all dwellers in cold, bleak districts might find a set of trees not only enjoyable, but profitable. It is now too late to pot trees; not so to obtain them already established from the trade, and having a full summer before us they might be shifted into larger pots, and, under cold house treatment, grown into marvels of fertility by the autumn. Another, and perhaps a less troublesome, plan would be to visit a good fruit-tree nursery, and mark a set of trees root-pruned last autumn for lifting and potting in October. Although the past winter and spring have been unusually severe, bush Peaches in a glass shed have set well with me, and where these succeed one is safely within bounds in saying Pears will do also. We at one time thought they were quite as impatient of fire-heat as Plums and Cherries; but this is hardly the case, as northern growers give them a climate equal to that of the south of France, always with plenty of air, and the size and quality of their fruit are all that the most fastidious can desire.

Pears in pots or planted out under a glass roof—which should be movable, as the latter cannot be turned out in winter—require nearly the same treatment as Plums; that is to say, they should be regularly pinched to induce the formation of fruit-buds; but the first pinching should be delayed until the growths are pretty well set, otherwise they will produce spray without end instead of flower-buds. The Quince stock enjoys rich living, solid and liquid, and produces hard gritty fruit where these things are withheld from it; it also does best and lasts longest when the union is close to the roots and buried beneath the soil or mulching. The selection of varieties is entirely a matter of taste, which can best be settled by the grower. Autumn and early winter sorts in districts where Pears can be grown at all should be sparingly represented, and late ones duplicated. New late Pears now are numerous, and many, no doubt, very good; but I should not object to a large houseful of Josephine de Malines, Winter Nelis, Thomson's, Knight's Monarch, and Easter Beurré. They are old, but they will take a lot of beating. W. C.

May weather.—Never was the following on the merry month of May more provokingly appropriate than on the 20th of this May:—

The skies are dull, the winds are chill,
No flowers are to be seen,
With branches bare, reluctant still
To wear their robes of green.

Alas! indeed, we only took the coverings off our fruit trees on the 19th. The wind veered further west and was a little softer, and so off the protection came, exposing to the blast a fine crop of Peaches, Nectarines, and Apricots. I am almost afraid to look at them to-day, after seeing and reading about the wreck, ruin, and litter made by the storm. More like November than May, is a very mild way of describing the storm of yesterday. The havoc made on land and water, in field and garden, in town and country, is something dismal. Ships wrecked, boats swamped, houses, buildings, and tents blown down or torn to rags; fruit and other trees stripped bare of blossoms or torn up by the roots; flowers beaten down level with the ground with icy cold floods of rain, cut into fragments with hail or covered over with snow. Such are some of the cultivator's experiences this 20th day of May. Unless winter ends soon it really seems as if it would run on until midsummer, and that we shall have to catch our crops as best we can in the month or so when the sun must needs melt the ice and drive away the hail and the snow.—D. T. F.

P.S.—My daughter writes from Fontainebleau, France, 7 a.m. Friday morning: "Torrents of rain, high wind and bitterly cold. It is just like winter and we all shiver. Weather still horrid, and the spring is with much difficulty slowly crowning the forest with verdure and fragrance." So that we are experiencing a very wide wave of cold.

FERNS.

W. H. GOWER.

LOXOMA CUNNINGHAMI.

THIS is a handsome, distinct, and at the same time a very remarkable Fern, and is the only member of the genus hitherto discovered. It is a native of New Zealand, where it may sometimes be found in moist woods. According to Sir Joseph Hooker, it is found in the Northern Island only, near the falls of the Keri-Keri River, at Coromandel, at Waitemata, and on the river Wangarei. Although there is but one recognised species, it is remarkable that specimens we have received from one district are invariably glaucous beneath, whilst the form we originally received is quite plain. If this character remains constant under cultivation, it surely will be sufficient to establish a varietal name for garden purposes. The fronds rise from a creeping rhizome, which is clothed with reddish brown hairs; they are triangular in outline, three or more times divided, from 1 foot to 2 feet high, coriaceous in texture, bright green on the upper side, slightly paler below in some plants; in others the whole under-side is of a milky hue; the involucre are situated in the notches of the pinnae and are reflexed. The plant should be fastened upon a block of sandstone, and its rhizomes surrounded with (not buried in) rough fibrous peat. It requires an abundant supply of water, and we have found the only position in which it thrives is in a close case with Filmy Ferns, although, from the consistency of the fronds, one would imagine it capable of withstanding a dry atmosphere. The plant has never been sent home in any quantity, so that it unfortunately is little known even in the best collections of Ferns. We have never been successful in raising this plant from spores; and should much like to hear if seedlings have been obtained in this country.

OUR NATIVE FERNS.

THE MOST DISTINCT VARIETIES OF THE MALE AND BUCKLER FERNS.—The variability of most of our native Ferns is characteristic, and affects some kinds to a much greater degree than it does others which are comparatively, or sometimes even totally,

The Broad Buckler Fern (*Lastrea spinulosa*).

free from variations. Although such species as *Lastrea spinulosa*, *cristata*, *annula*, *rigida*, *remota*, and *palustris* may be said to have entirely retained their original form, from which no deviation worthy of special attention has been noticed, the Mountain Buckler Fern (*Lastrea montana*) has shown a certain tendency to sport, and has produced a few varieties, some of which have been considered of

sufficient importance to occupy a permanent place in collections, and to deserve the careful attention of the late Mr. Thomas Moore, who named and described most of them. Among those we must first note its crested form (*Lastrea montana cristata*), whose fronds, as large as those of the species, have their apex beautifully tasselled or crested; the same character is also apparent at the points of all

The Rigid Buckler Fern (*Lastrea rigida*).

the pinnae, which are equally crested, but of course to a less degree, though sufficiently so to render the plant very attractive. Then there are the crisped and truncate forms, the first of which, *L. montana crispa*, has its pinnules or secondary divisions slightly pinched or puckered inwards, giving the whole frond a rather wavy or crisped appearance; whereas in the second, *L. montana truncata*, the fronds, of the same length and breadth as those of the species proper, have their points, and also the points of each primary division or pinnae, abruptly ended, as though bitten off, and the point of the mid-rib of each projecting awl-like beyond the foliated part of the frond. But the form of the Mountain Buckler Fern by far the most distinct, and also the most interesting, is that known under the name of *L. montana Nowelliana*. This thoroughly permanent variety, originally found in North Wales, is of so extraordinary a character, that anyone only moderately acquainted with the species

The Mountain Buckler Fern (*Lastrea montana*).

would be puzzled to say to which type it is related, as so very little possessing the characters belonging to the species is left. Its fronds, which vary from 18 inches to 24 inches long and from 4 inches to 6 inches in breadth, are furnished with very narrow pinnae and pinnules, extremely abbreviated, variously eroded and crenulated, often curiously hooked and horned. This permanent departure

from the type is all the more remarkable that *Lastrea montana* is generally accepted as one of the species of Buckler Ferns very little given to variation.

THE BROAD PRICKLY-TOOTHED BUCKLER FERN (*Lastrea dilatata*) has only produced a few varieties deserving of special notice, but some of these are truly remarkable; such, for instance, as its crested and crisped forms, the former (*L. dilatata cristata*) differing from the species solely by its broad, oval fronds, very spreading, having at their point and also at the points of many of their primary divisions once or twice-divided short, broad, flattish crests. The variety *polydactyla* is still an improvement on this curious form, showing a much greater development of the crests, which are disposed with constant regularity on each side of the frond. The crisped form, *L. dilatata dumetorum*, is a small-growing, very pretty variety, whose fronds, seldom exceeding 10 inches to 12 inches long, have a particularly pleasing, crisp appearance, owing to the upper surface of their secondary divisions being of a pinched and puckered nature, quite distinct from all other known varieties. Among the several diminutive forms of dwarf habit deviating from the original *Lastrea dilatata*, one of the most interesting, on account of its neat, tufted habit and of the peculiarity of its growth, is the branching form *L. dilatata ramosa*, which usually produces fronds either branching-stalked and then twin-fronded, or branching half way up or near the point

The Marsh Buckler Fern (*Lastrea palustris*).

with secondary divisions crispy, closely set, overlapping, and spiny-toothed. We have in *L. dilatata lepidota* a Scotch variety of great decorative value, and which appears to have entirely lost the characters belonging to the species from which it is issued, as it is of a dwarf habit, and its lovely fronds, which seldom attain more than 10 inches in length, are very spreading and almost triangular in shape and quadripartite, or four times divided, near the base; the whole fronds being thus finely incised through the ultimate or last divisional parts being very small, the plant possesses a very elegant appearance, totally different from that assumed by any other form of *Lastrea dilatata*.

The common Male Fern, however, is of all the species of *Lastreas* that which is credited with the greatest number of abnormal forms of all sorts, some of which are extremely beautiful. That species has under cultivation shown a greater tendency than any of the others to produce crested forms which are very constant, and though very numerous are also exceedingly ornamental. The *Lastrea Filix-mas cristata*, certainly one of the most distinct and deservedly very popular forms, was first found in a wild state in the west of England, and although one of the oldest varieties known, it is also justly acknowledged as one of the most decorative, and one whose good standing qualities annually increase in value, especially where the plant is subjected to pot culture. This variety attains a size about equal to that of the common

species, but it is of a much more graceful habit, as each spreading frond, 8 inches to 9 inches wide, is arching, from the apparent weight of its often very large and many times short-branched terminal crests. Each of the primary divisions end in a

The Crested Buckler Fern (*Lastrea cristata*).

similar, though smaller branched crest, thus forming on the outline of the frond a border of pretty crispy miniature crests. *Lastrea Filix-mas cristata angustata* is a very elegant form of the variety just described, but with fronds very narrow and the pinnae so reduced as to form two almost parallel rows of compact tassels, diminishing in size as the frond tapers to a terminal crest. Among the other numerous crested forms of the Male Fern, one specially notes *Lastrea Filix-mas Jervesi*, *furcans*, *Iveryana*, *Mapplebecki*, and *caudata cristata*; but the most striking variety is undoubtedly that called *grandiceps*, which is the most gigantic of the whole section of crested kinds. It grows to a size quite equal to that of the species, its fronds often measuring 24 inches high by 5 inches or 6 inches in width, but their apex is densely ramose and crested in a different way to those above described, and, indeed, in a completely distinct manner from any other known variety, inasmuch as the cresting process begins from a few inches from the top of the frond, where the midrib branches three or four times, each of the ramifications being furnished with pinnae closely set and crested like those of the lower part of the frond, the top of which is gracefully pendulous. Of the equally numerous non-crested forms of this Fern, one of the most distinct is *Lastrea*

The Male Buckler Fern (*Lastrea Filix-mas*)

Filix-mas Bollandiae, a variety with somewhat wavy fronds, whose primary divisions are deeply cut into secondary ones, which are deeply toothed and connected by a leafy wing to the midrib. *Lastrea Filix-mas foliosa* is another exceedingly distinct

variety with short pale green fronds borne on naturally short stalks. It possesses a densely leafy appearance produced by the overlapping nature of the primary divisions, as well as by the slightly twisted character of the pinnales, which in some cases entirely conceal the midrib. In the variety *Pinderi* we have a nearly erect form whose fronds possess a peculiarly narrow outline on account of their being short-stalked, about 4 inches wide in the middle, and tapering above and below. The small or dwarf-growing forms of the Male Fern are best represented by the varieties *pumila* and *Schofieldi*, neither of which seldom exceeds 4 inches in height. They have short-stalked, nearly erect, lance-shaped fronds of a dark green colour, with their points usually once or twice forked.

S. G.

ORCHIDS.

W. H. GOWER.

RESTREPIAS.

THIS is a small-growing genus nearly allied to *Pleurothallis*. It contains numerous species, all of which are dwarf in habit, and although they cannot be classed with showy Orchids, they are, nevertheless, exceedingly curious and interesting. *Restrepias* are all natives of Tropical America, and are found growing at considerable elevations. Under cultivation they thrive under the same cool treatment as *Masdevallias*, and for this reason, as well as the fact of their being dwarf in growth, they will be found fit subjects for Wardian case culture. These plants should be fixed upon a small block of wood with a little *Sphagnum Moss*, or placed in a very small basket and suspended. The half of a Cocoa-nut shell forms a capital receptacle for them, and, indeed, many other small-growing Orchids that, like the *Restrepias*, do not take kindly to pot culture may with advantage be grown in these. A moderate supply of moisture is requisite during the whole season, as they are continually growing more or less. The following species deserve more extended cultivation than they have hitherto received:—

R. ANTENNIFERA.—The best form of this plant produces large and handsome flowers. The species was originally discovered by Humboldt in New Grenada, where it grows upon the trunks of trees, at an elevation of from 6000 feet to 8000 feet. It has stem-like pseudo-bulbs, which support a single ovate-oblong, leathery, dark green leaf, the whole plant seldom exceeding 8 inches or 9 inches in height. The flowers are produced in great abundance, upon long foot-stalks which issue from a rough scaly spathe at the base of the leaf; these are exceedingly curious and very persistent. The dorsal sepal is lengthened into an erect tail-like appendage, yellowish-white streaked with purple; the lateral ones being broad and long, connate for the greater portion of their length, but bilobed at the tip, having the appearance of a large lip; reddish crimson in colour, profusely dotted with purplish lake. Petals small and narrow, and, like the dorsal sepal, clubbed at the apex; lip small, same colour as the lower sepals. It is almost a perpetual bloomer.

R. ELEGANS, as its name implies, is a beautiful form, similar in habit and appearance to *antennifera*, although the flowers are scarcely so large. They are borne erect upon long foot-stalks; dorsal sepal tapering into a clubbed tip; lower sepals joined to nearly the apex, yellow within, tinged with purple on the outside, streaked with lines of close-set, large reddish purple spots; petals filiform, and slightly clubbed at the tip. It grows at some 6000 feet elevation in Caraccas.

R. VITTATA is a smaller growing plant than the preceding, which it otherwise much resembles, and under which name it is frequently to be found in collections; the large connate sepals are yellow, ornamented with lines of purple spots. Colombia.

R. LANSBERGII. This is a still smaller plant, but so exceedingly beautiful that it well deserves the

attention of the amateur for culture in the house. It flowered with us for the first time in England about the year 1851, and it has remained a favourite ever since, notwithstanding the numbers of large showy flowered Orchids that have since been imported; the flowers are produced at the back of the leaf, dorsal sepal and petal clubbed, the latter pendent, and, like the lateral sepals, bright shining yellow, dotted with purple. It comes from Guatemala.

CATTLEYAS AND ODONTOGLOSSUMS AT THE WOODLANDS, STREATHAM.

THE Cattleya house in Mr. Measures's garden just now presents a perfect galaxy of beauty. Imagine a display of upwards of 1500 expanded blooms of *Odontoglossum* (*Miltonia*) *veillardii*, and about an equal number of buds just opening, some of these being very fine varieties both as regards colour and size. On some of the plants are highly coloured flowers, measuring over 1½ inches across, whilst their vigour is well exemplified by one plant with but a single growth, which is bearing twenty-seven enormous flowers. Amongst them is a distinct form which leads one to hope that we have not yet seen the last of the variations of this species. Although we have in *O. v. Measuresianum* a pure white flower, and in *O. v. superbum* a flower of intense colour, the variety now flowering at The Woodlands, and which has not yet been distinguished with a varietal name, has the lip dotted all over with deep purple spots. These plants are grown all the year round with the *Cattleyas* and *Lælias* in a house kept at an intermediate temperature between the East India house and the houses devoted to the *Odontoglossums*, *Masdevallias*, and other high mountain Orchids. These *Odontoglossums* are exposed to strong light, but are never sprinkled overhead, the necessary moisture being supplied by pouring water upon the stages and damping the sides of the pots. The *Cattleyas* and *Lælias* with which the *Odontoglossums* are associated are treated exactly in the same manner, the robust growth and the abundance of flowers affording ample proof that their surroundings are congenial. Of these there are nearly 400 blooms open, the kinds being chiefly *C. Mossie* in great variety, *Lælias purpurata* and *elegans*, *Cattleya Skinneri* and its lovely pure white form (*alba*), *C. Aclandii* and *intermedia*, and *C. Mendeli*, amongst which are some remarkable forms, including the grand variety known as *C. Mendeli Duke of Marlborough*, with flowers upwards of 7 inches across, the sepals and petals, which are delicate lilac, whilst the large-frilled lip measures more than 4 inches over, and is wholly rich crimson-purple, this colour extending far back into the throat, where it is flushed and streaked with orange. *Odontoglossum citrosum* still continues to constitute a remarkable feature in this garden in a small, very light house, in which there is no centre stage. These plants, on which there are about a hundred long spikes of bloom, are suspended from the roof, forming a charming grove of beauty; the colour varies in different plants, from one with pure white flowers to one with rosy sepals and petals, with a large, almost crimson lip. This is the second batch of these plants which has flowered this season with Mr. Measures, the succession being obtained by keeping a portion of the stock cool and very dry. Another rare and remarkable plant blooming here is *Cypripedium Wallisi*, which is a near ally of *C. caudatum*, the sepals being pale yellow, lip almost white, and the long, tail-like petals are 18 inches in length and are still growing. The brilliant flowers of various *Masdevallias* are specially attractive, but one form of *M. Veitchii* is remarkable, and perhaps unique; the flower is large, the ground colour being yellow (of as bright a shade as the blooms of *M. Davisii*), the dorsal segment being flushed with purple, the same colour extending in a single line down the lower segments.

G.

Odontoglossum Harryanum.—This is a rare and extremely handsome species, and quite a departure from the ordinary type of the genus. It flowered last autumn for the first time in England with Messrs. Veitch, of Chelsea. The spike is very

stout, bearing twelve to fourteen large flowers, which measure some 4 inches across; sepals and petals chestnut-brown, streaked and transversely barred with rich yellow; lip oblong, three-lobed, white heavily streaked with bluish purple, pure white in front; crest much fringed, bright yellow. This plant appears to be a vigorous grower, in habit much resembling *O. Halli*. A quantity of this species recently imported was sold by Messrs. Protheroe and Morris, the prices ruling high. Its native country is at present known but to very few.—G.

ROSE GARDEN.

T. W. GIRDLESTONE.

NEW ROSES FROM IRELAND.

A HANDSOME coloured plate, in which their new Hybrid Perpetual Rose, Earl of Dufferin, is represented as a very finely-formed, dark shaded crimson flower, has been issued by Messrs. Alex. Dickson and Sons, of Newtownards, Ireland.

Of all flowers probably none is so difficult to represent exactly as a modern Rose, and in despair of ever making an artistic presentment in colour, those who prepare figures for reproduction in the form of coloured plates are sometimes liable to paint what they think the florists would like to see rather than that which actually exists. In the present instance, however, no exaggeration need be feared, as, considering the number of first-class certificates (not less than six) that have been awarded to Earl of Dufferin, and its unprecedented record of winning the premier prize as the best bloom in the show on two occasions actually before it had been distributed, this variety must be very good, and the portrait is additionally likely to be a characteristic presentment, having been drawn from flowers from cut-back and not maiden plants.

In an interesting letter on the subject of seedling Roses, Messrs. Dickson mention that Earl of Dufferin was raised in 1882 from seed produced by a cross between Horace Vernet and Charles Lefebvre—parents which, at any rate, should ensure flowers of fine quality and colour in their progeny; and, like all Roses of dark (or, for that matter, any other) colour, this variety is said to produce the handsomest blooms when grown on Brier stocks.

Another Hybrid Perpetual, Lady Helen Stewart (named by the Marchioness of Londonderry after her little daughter), was raised from seed which resulted from a cross between General Jacqueminot and A. K. Williams, and is described as a very vigorous and erect plant, producing flowers of a brilliant crimson colour with a very stout, smooth petal.

Judging from flowers of Miss Ethel Brownlow received on May 10, having been cut from plants grafted only the last week in February, this Tea-scented variety, which completes Messrs. Alexander Dickson's present trio of novelties, in addition to being extraordinarily free-blooming, has very full and well-formed flowers, which recall Catherine Mermet both in outline and colour to some extent. The rose colour, however, appears fuller than in Catherine Mermet, and the new variety is said to be far more free-flowering. It was the outcome, in 1881, of a cross between Madame Lambard and President, and it carries its flowers erect, like the former, on a stout stem, wherein it has an undoubted advantage over Catherine Mermet, whose pendulous habit is often the cause of the disfigurement of many a fine bloom.

Two very noticeable points in Messrs. Dickson's interesting communication on Rose raising

are the importance attached to the necessity of the Rose seed being thoroughly ripe, and the desirability of saving seed from flowers that have been artificially fertilised. That all seed should be well ripened goes, of course, without saying; but Messrs. Dickson's experience leads them to believe that thorough ripeness of the seed sown is the most important factor in obtaining Roses of good constitution, and they express the opinion that if this (thorough ripeness) is secured, "even weak growers will give strong growers as progeny." In regard to the second point, it has been the experience of most raisers of Roses that nearly all the seedlings produce only single or semi-double flowers; but then the immense majority of seedlings raised have been from chance heps gathered at random. Messrs. Dickson have found, by practising artificial fertilisation for a series of years, that the tendency among plants raised from seed so produced is rather in the opposite direction, and that many seedlings have flowers so full that they cannot properly expand.

It appears that the record is preserved of all the seedlings raised at Newtownards, whether good or bad, and the accumulation of evidence thus obtained must ultimately prove a most valuable addition to our singularly meagre stock of reliable information on the subject of Rose raising and cross-fertilisation; while it is obvious that seedlings emanating from an establishment where the raising of new Roses is a matter of such elaborate care will be awaited with keen interest by all Rose growers.

FORTUNE'S YELLOW ROSE.

IN the bud state for button-hole purposes I find this Rose is more useful than many other sorts, and equal in favour with Maréchal Niel and realises quite as much in the market, for which purpose I am astonished that it is not more grown. I find that with every order for Roses comes the following request: "Send me more of that peculiar coloured Rose," and we do not want better evidence of its popularity than the market demands afford. It is not, however, a reliable Rose to plant in the open, as it is too tender; even on walls with a south aspect it cannot be depended upon to stand through the winter. This is to be regretted, as, like many other sorts, the colour of the flowers is much deeper in the open air than under glass. When grown under glass it is a strong growing Rose, suitable either for training on wires or on pillars. We have it this season trained up a pillar 10 feet high in a large house with the top branches allowed to grow at will all last summer. Grown in this way it forms a very pleasing feature, and the number of flowers it has produced has been surprising. The half open bud is charming, and only single blooms are produced on each shoot; but supposing a plant makes shoots 6 feet long this summer and they are not pruned, nearly every bud along the whole length of that shoot will produce a single flower next year. The system of pruning that must be adopted to induce it to flower satisfactorily is therefore to prune as soon as it goes out of flower, and not to use the knife again until next year, unless it be in the case of stilly trained plants which have made vigorous growth. I have sometimes found it necessary to thin out the weakest shoots in the autumn, leaving the strongest the whole of their length; by letting in more light and air the wood which is left gets better ripened and in consequence it produces a greater number of flowers. I find that it is better to grow it on pillars. This Rose is increased from cuttings as readily as *Pelargonium*. If the shoots which have flowered are made into cuttings at once, and the cutting pots placed in bottom heat on a Cucumber or Melon bed, they will be sufficiently rooted in three weeks to be potted off. I cannot say that it is as suitable for growing in pots as when planted out, but as compared to other Roses it flowers quite as freely, only it requires more root room. Given a fairly large pot, the growth

made under glass in a light, airy house, and the long shoots allowed to grow pretty much their own way, plants in 12-inch or 14-inch pots will produce a quantity of flowers; there is, of course, an advantage in having a few large specimens in pots, as the season can be prolonged. It does not submit kindly to hard forcing, as when forced early the buds, which are never large, are too small, and they are also deficient in colour. There is still time to plant this Rose and secure a pretty good growth this season, but they require to be at least three years old to make effective objects. J. C. C.

MARÉCHAL NIEL ROSE FAILING.

THE only difficulty in dealing with the case given by Marshall Bros. (p. 414) arises from the unequal behaviour of different plants in the same house under the same treatment, and the difficulty of knowing exactly what is meant by the shoots cankering after making growths of 5 feet or 6 feet. As, however, it is stated that the shoots first turn yellow and then gradually die away, the disease can hardly be canker or warts, as generally understood. Accepting the definition of the disease given by your correspondents, it may be produced or aggravated by one or all of four causes that are more or less obvious on the surface of this case as stated (p. 414)—deficiency of light, want of air, lack of drainage, and excessive strength of manure water. As to the first, as the Roses are trained on wires running round the sides of the path, and nothing is said of the height of the house, nor of the side walls, which are opaque, it may well be that the growing shoots droop, turn yellow, and die back for lack of light. Everyone familiar with the character and idiosyncrasies of this fine Rose knows how essential brilliant light is to the strength and maturity of its fast-growing branches. It can hardly be trained too closely to the roof if a maximum of strength, beauty, and stability is to be achieved. The shoots seldom look yellow or die back as if affected by a sort of gangrene if they are run up close to the roof; the light strengthens the shoots and gives them stability as well as verdure. Want of air may be another cause of the malady. Nothing is said of roof ventilation, but we are told that there are no side lights, only ventilators which have recently been nailed up. Under such conditions in a stagnant atmosphere far from the light, it is not surprising that succulent growing shoots of the Maréchal Niel or any other free-growing Rose become sickly, yellow, and gradually die away.

Insufficient drainage would intensify the ill-effects of lack of light and want of air. We are told that the Roses are planted in good loam, and this may be good or bad for them, as it rests on a porous or impervious bottom. Good loam may quickly be converted into something akin to mud if it rests on stagnant water or mud. The roots penetrating a wet border or bottom would speedily react on the tops with such disastrous symptoms and results as your correspondents describe. Finally, the manure water may be over-strong. Few things vary more widely in quality than farmyard manure water. It may be weak almost as coloured rain water, or dangerously potent as water of horses outside the stable door. The latter is totally unfit for the roots of even the most gross-feeding Maréchal Niel Roses, unless diluted before use with at least ten to one of rain or other clean water. There is no form of manure water that needs more judgment or care in its application than farmyard liquid, and unless employed with extreme caution it had better not be used for flowers at all. Assuming that the three other influences might be working together to promote disease in these Roses, over-strong manure water would add to and aggravate their force, and introduce another and a greater danger than either.

To all this it may be urged that the Rose plants or branches, for it is not clear which, are not all alike affected, as some are growing and flowering splendidly. This only may prove that there are generally such exceptions to be met with, and that these by no means disprove the foregoing estimate of the probable causes of the disease. Plants occasionally diverge from their natural type, but these exceptions only confirm the rule that their nature is to reproduce their like; so certain conditions

produce certain results, though some plants, or parts of plants, may be able to resist or overcome the legitimate effects of such conditions.

Having answered, to the best of my ability, the question of what is likely to produce canker under such circumstances, I would give a decided negative to the second question, "whether to go on growing this Rose in such a frame under such conditions as those stated," and would advise that those conditions be altered at once, in so far as the giving of more air, and placing the shoots closer to the glass are concerned. The drainage must also be improved if needful, and more care exercised in relation to the application of manure. Weak and often is the only safe rule for this, even in regard to such gross growing and rooting plants as the Maréchal Niel Rose.

One more point deserves notice. The house is said to be large and cool. Does the latter phrase mean that it is wholly unheated? If so, the disease may be produced, or greatly aggravated by sudden depressions of temperature below the freezing point after the young shoots are in full and vigorous growth. The Maréchal Niel is so readily excited under glass, especially in houses with little or no ventilation, that early growth, succeeded by frequent chills and consequent checks, may very probably result in gangrene and dying back, as your correspondents describe. This Rose is so popular and so valuable, and also subject to so many and various accidents, that the case deserves the fullest possible consideration, and hence the semi-exhaustive manner in which I have treated it. D. T. F.

Maréchal Niel on south-east aspect. Our Maréchal, planted upon a south-east wall, has stood the winter uninjured, and is showing plenty of flower. Another one, planted upon a south border, has also stood the winter unprotected, and is also showing flower, though no earlier than the other. Tea Roses on the wall of an east terrace have stood well, and are now making some strong growth and look the picture of health. These have been protected with Yew and Box branches, with a mulching over the roots. Standard Hybrid Perpetuals have given most anxiety. They have stood rather badly; we have had to replace a good many, but they are doing very well now, and fine weather without the piercing east winds will soon give us plenty of flowers. W. A. COOK, *Holme Wood, Peterborough.*

Hardiness of Tea Roses.—"D. T. F." can hardly have read the article on page 433 very carefully, or he would not have been under any misapprehension as to the temperature there given, for the difference between that temperature of 70° Fahr. and the 25° Fahr. assumed by "D. T. F." is sufficiently noticeable. The objection to the suggested use of Cocoa fibre as a winter protection for Tea Roses is that on heavy land it keeps the soil too damp and close, but on light land it is good where the plants cannot be earthed up. As a summer mulch it is excellent on light land, either to retain moisture, or where Tea Roses are mulched with cow manure to make the beds sightly and pleasant to walk upon; but in the last case it cannot be utilised after it has been round the plants all winter without being removed and replaced—a process by which its employment would involve very considerable labour. A better plan is, where the earthing up is thought to leave the roots too thinly covered, to lay a thick mulch of long manure in the furrows or intervening spaces between the plants, so that the roots may be kept warm, and at the same time when the ground is levelled down in spring the manure disappears from view. Spruce boughs are undeniably good protection, but when they are employed it must be borne in mind that they require a great deal more fixing than Bracken to secure them from the action of wind, and even when cut with stems long enough to be thrust firmly into the soil they are liable in a gale to be blown round into positions in which they are useless to the plants they are meant to protect, unless very securely fastened.—T. W. G.

Locality of Rosa macrantha in the open.—"W. T. W. G." kindly give some indication of the whereabouts of his bush and pillar specimens of this charming Rose? I

have no desire to pry into such matters as his name and address. The county or some other rough index to locality will suffice, and much obliged, HORTIC.

Rose leaves diseased.—I herewith enclose you a few leaves from Beauty of Waltham grafted on Manetti stock. The plant continues to make growth, but the leaves go as enclosed, and fall off. I should be glad if you would tell me what it is, and the cure. They are planted in borders under glass, but no heat. I have about forty plants in the house, but this is the only one affected. It suffered the same last summer.—WM. LIGHTBOWN.

. Your Rose is attacked by a fungus, probably *Peronospora sparsa*. Is it in a less healthy position in the house than the other plants as regards ventilation and soil? Syringe well with from a quarter to half an ounce of sulphide of potassium in one gallon of water, and if the plant is not growing freely give some liquid manure.—G. S. S.

EDUCATION OF GARDENERS.

I AGREE with those who think a knowledge of all the "ologies and 'statics" enumerated in THE GARDEN not long since unnecessary to a gardener, especially in these days, although some of them, like geology, for example, are delightful to study and think about in themselves. I do not even admit that any extensive knowledge of botany is needed, but familiarity with vegetable physiology and some acquaintance with the nature and chemistry of soils is invaluable. The rest depends on one's own common sense and observation. I am speaking of practical gardening only, not of landscape gardening, which needs a faculty that none of the sciences supply. I certainly would not at the present advise any young gardener to lose time studying the dozen or more subjects enumerated by "H. J. H." (p. 374), and I never contemplated such a thing when I suggested a prize to encourage young men to learn their business (p. 271). With the handy-books and guides at his disposal now-a-days, all a young man wants to become a good gardener is a well-selected, small library, a good pair of hands, and a fair share of brains. Given the last two, the other will come. I have had to do with well-educated "clever" young men often, and when they happened to be good workmen as well, which is not always the case, and endeavoured to follow out and anticipate their masters' ideas and orders, and manage generally, we got on famously. When the last qualification was wanting, it was bad for somebody. It is a great thing to start fair in a good garden and under an appreciative head gardener.

We hear much of the superiority of foreign gardeners as regards their education, and I admit they seem to secure appointments abroad and elsewhere on account of their educational attainments, which are not to be despised or ignored on any account. To sum up the matter, a man who can work himself, who knows when others do their work, who is a fairly good reader, writer, arithmetician, and who can draw plans to scale, is fit for a gardener of the highest class anywhere.—J. S.

"Miltonia" appears to have been extremely unfortunate in his choice of young men when he says he generally finds the leaves of THE GARDEN uncut after being in their possession for a month. This is a sad state of things, but you will be glad to hear that it is not always the case; at least three copies of THE GARDEN are taken in here every week, and I venture to say they are cut within a few hours after they arrive. Perhaps "Miltonia" could improve matters somewhat by giving a little fatherly advice or by exercising a little gentle persuasion; if so, I am sure his time would be well spent. Indeed, I cannot agree with "Miltonia" when he says "the majority of young gardeners care very little about reading." During the fourteen years I served as an under gardener in private gardens I shared quarters with about forty young men, and I can safely say the majority of them were well read and thoroughly intelligent men for their station in life, and a good number of them are now filling responsible positions as head gardeners. I am not surprised to hear that young men take but little interest in a book that treats only of "outdoor

hardy stuff," seeing that this useful class of plants has been pushed on one side to make room for subjects of a less permanent character, but, happily, hardy plants are now rapidly coming to the front. We have plenty of gardening periodicals at present, and if "H. J. II." requires books treating upon the subjects he mentions (p. 374), he will readily get them at Cassell's. A good sound education is of great advantage to a gardener, but to cram his head with a lot of useless technical knowledge is to hinder rather than help him in his career.—E. B. L.

—Surely "Miltonia" in THE GARDEN (p. 414) does not mean what he has penned; if so, my short experience of young gardeners is quite the reverse, for I find no class of workmen so given to reading and study. After living for several years in some of the best places in the country I can candidly say I never saw any horticultural papers go uncult for one day, much more a month. In the rooms from whence I write there are six young men living, and as soon as the papers arrive it is generally a rush to have the first look at them, and as regards studious habits, some study botany, some geometry, and some literature. Therefore, what foundation "Miltonia" has to judge the majority of us young gardeners on I cannot see. I must, however, admit that there is a tendency among young gardeners to disregard the cultivation of hardy plants as well as that of vegetables, but such are not true horticulturists, and rarely make good gardeners.—C. COLLINS, *Howick*.

** No good can come from any further discussion of this question. The way to become a good gardener is to learn and work in good gardens; to take advantage of the best books and papers of the time; to keep the eyes open and the head clear, seeing as much as possible of every kind of garden, including the smallest. When vegetable physiology is really known to those who study it, we shall be able to judge of its use to gardeners. ED.

TREES AND SHRUBS.

VARIETIES OF PORTUGAL LAUREL.

(*CERASUS LUSITANICA*.)

OF a shrub so common and so well known as the Portugal Laurel there is no need to write about, but it seems to me that the varieties of it are very little known, and particularly the small-leaved form named *myrtifolia*, a name not very applicable, inasmuch as its foliage is no more like that of the Myrtle than the common Portugal Laurel is. A shrub so distinct and so handsome as this so-called Myrtle-leaved variety is decidedly worth knowing. It differs from the original by its smaller, longer, and narrower leaves, which, moreover, are more closely set on the branches, and therefore may be distinguished at a glance. Another and important characteristic of this *myrtifolia* variety is its tendency to grow erect; consequently it is not a difficult matter to train a young bush of it to form a symmetrical cone or pyramid, and in either shape it possesses a handsome appearance, and more like the Bay than anything else. In some styles of formal gardening primly trained cones and pyramids of the Myrtle-leaved Portugal Laurel are invaluable, as they are slow in growth and may be kept symmetrical in shape with very little trouble. I have had occasion to plant some cone-shaped specimens of this variety lately in a geometrical garden, and the effect they produced is remarkable, as they are so different from Yews, Hollies, Box or any of the Conifers. In the Bagshot Nursery a good deal of attention is paid to cone-shaped Myrtle-leaved Portugal Laurels, and the long lines of fine specimens attract the attention of every visitor. In an untrained state this variety is of much the same habit of growth as the ordinary

Portugal Laurel, though its smaller and denser leafage makes it different in appearance. It is about the same tone of green, is quite as hardy, and of the same rate of growth. The varieties named *angustifolia* and *ornistoniensis* are, so far as I can make out, identical with *myrtifolia*. A variety with short and rather broad leaves and of thicker texture than usual is called *crassifolia*, but it possesses no special feature to render it superior to the original type. The variegated form (*variegata*) is not particularly beautiful, and I cannot remember ever seeing a bush of it that had not branches of green leaves intermixed with the variegated, which always gives it a piebald appearance. A very handsome variety is that named *azorica*. It is altogether of stronger growth than the original, with larger leaves and of a richer green. The twigs, moreover, are of a decided reddish tinge, a hue which the young leaves assume in spring. Though a native of the Azores, it is found to

and its flowers are a mixture of yellow and reddish rose. It is called Gordon's Flowering Currant because the late Mr. Gordon, when he was chief of the arboretum at Chiswick, in olden days, used to pay a good deal of attention to the genus *Ribes*, and himself raised this hybrid.—W. G.

The Mahaleb Cherry.—Among all the trees of the Cherry and Plum tribe now in bloom the Mahaleb Cherry (*Cerasus Mahaleb*) stands out prominently by reason of its peculiar growth and profusion of bloom, and yet it is a tree very seldom seen in private gardens. At the present time some trees of it in the arboretum at Kew are entirely masses of white blossom, the leaves in the present state being very small and inconspicuous. It is one of the smallest-flowered of all the Cherries, but what they lack in size they make up in numbers, for every tiny twig carries a dense cluster of bloom, which is, moreover, strongly scented. It is a small-growing tree, with a dense, bushy head, and rarely is more than 20 feet or 30 feet high. The leaves are heart-shaped, not unlike those of the

The Portugal Laurel (*Cerasus lusitanica*); flowering and fruiting branches with detached flower and fruit, natural size.

be as hardy as the common form inhabiting the mainland.

All the varieties thrive under the same conditions as the type, preferring shelter to exposure, a light soil to a heavy, and a moist soil (not wet) to a dry one. The finest specimens one meets with in very old gardens are those growing under the most favourable conditions as to soil and shelter, and among all the beautiful Evergreens with which our gardens are enriched there are few more beautiful than a luxuriant Portugal Laurel, and much of the beauty of old English gardens is due to this beautiful, yet oft abused, Evergreen.

Ribes Gordonianum.—Gordon's hybrid Flowering Currant may not be considered by some so beautiful as the common *Ribes sanguineum*, but it is different from it, and that is a great point, for while the brighter flowering *sanguineum* is so common, Gordon's sort is very seldom seen, and therefore always attracts attention. It is exactly half way between *sanguineum* and the yellow *aureum*,

so that it may be at once recognised when out of bloom. There are a few varieties of it, none being more remarkable than that named *pendula*, which is of a decidedly weeping habit of growth, and when in full flower, as now, is extremely graceful, and particularly beautiful as a lawn tree, and a more suitable tree for a small lawn could not be named. Like most other trees of the Cherry tribe, the Mahaleb is specially adapted for planting on poor, dry soil, and this is well exemplified at Kew, where the soil is both poor and dry. The Mahaleb Cherry is a South European tree, and has been cultivated in England since 1711, and in the neighbourhood of London there are some fine specimens of it in old gardens—Syon, for instance.—W. G.

Spiraea prunifolia fl. pleno.—This *Spiraea* is one of the first to bloom, for even in this late season it was in full flower around London by the middle of May, at which time the earliest of the flowering Currants were on the wane. This *Spiraea* forms a remarkably pretty shrub, for if so planted that there is ample room for its full development, it will reach a height of 6 feet or thereabouts, and assume the character of a rather dense bush. The long, slender, arching shoots give it at all times a

light and elegant appearance. A great additional attraction is furnished by the blooms, which are quite double, pure white in colour, and arranged in little clusters along the branches for a considerable portion of their length. The neat lance-shaped leaves are of a cheerful shade of green, and in autumn before they fall are very brightly coloured. Another species that flowers about the same time as this last is *S. Thunbergi*, and the general characters of this are something like those of *S. prunifolia*. *S. Thunbergi*, however, does not attain to the same dimensions, and the blossoms are single. Both these *Spiræas*, in common with most of the shrubby members of this genus, are seen to the greatest advantage in fairly good soil and in rather a moist situation. At the same time a little judicious pruning is of great assistance in helping the display of bloom, for after a plant has been established in one spot for some time it often becomes a thick mass of slender twigs, which are greatly benefited by being thinned out, as it is on these long wand-like shoots that the greatest display of blossom is produced. The curious Siberian *S. laevigata*, which out of flower might be mistaken for a *Daphne*, is now in bloom, but though very distinct, its ornamental qualities are much inferior to the others.—T.

Andromeda japonica. This delightful little evergreen shrub is now conspicuous by its new shoots, which being of a bright roddy tinge contrast beautifully with the deep green of the old leaves, so that the bushes are scarcely less attractive now than when hung with drooping clusters of waxy white Lily of the Valley-like flowers. It is certainly a shrub that (to use a common expression) deserves to be better known. Many think it is a tender plant, but it is unquestionably quite hardy in the neighbourhood of London and south of it. The past winter has had no effect upon it whatever at such widely separated places as Knapp Hill and Kew.—W. G.

The tall Arbutus, or Strawberry tree.—The blooms of this handsome North American shrub, or small tree, are among the flowers of the week, and a very handsome appearance they make, as both foliage and bloom are beautiful. It is very different from the common Strawberry tree (*Arbutus Uuedo*), but a good deal like *A. Andrachne* in growth and foliage. Its leaves are broad, of leathery texture, and of a luxuriant shining green. The flowers hang in drooping clusters, each being urn-shaped and of a delicate greenish white. It is one of those trees whose beauty is not developed until they are fully grown; therefore, it is generally in old gardens that it is seen to perfection. It comes from the north-west coast of North America, being one of the introductions of the traveller Douglas sixty years ago. At Kew it is hardy, but it is undoubtedly tender in heavy soils to the north of London.—W. G.

A new variety of Spruce. Messrs. Veitch exhibited at South Kensington on Tuesday a new variety of the Norway Spruce that promises to be a most valuable addition to ornamental trees. It is named *Abies excelsa mutabilis*, presumably on account of the young shoots being of a pale green, changing at length to the normal deep green of the ordinary Spruce. The contrast between the tender green of the young shoots with the dark green of the old foliage is most remarkable, and one can imagine how effective it would be on a lawn. The new variety bears no resemblance to the variety *aurea*, inasmuch as the foliage of this is yellowish, even when fully matured, and instead of being ornamental gives the plant a sickly appearance. But in *mutabilis* the foliage at length returns to its normal green. It is, perhaps, not wise to form a hasty opinion of a new tree, but we shall be deceived if this one does not prove of great value to the landscape gardener.—W. G.

SHORT NOTE.—TREES AND SHRUBS.

Cupressus Lawsoniana in bloom.—Generally speaking, the male blooms of the different *Cupress* play but a very small part in the embellishment of the plant, but an exception must be made in the case of Lawson's *Cypress*, the beautiful plume-like branches are in some specimens

quite covered with the bright crimson male catkins, which cause the plant to be of quite a different hue. Not only do the feathery branchlets retain their freshness for a long time in water, but even these blossoms keep bright for a considerable period.—T.

DOUBLE VARIETIES OF AMERICAN AZALEAS.

THE group of these which Mr. Anthony Waterer sent to the meeting of the Royal Horticultural Society on Tuesday was one of an extremely interesting character. Though *Azalea nudiflora*, the progenitor of our deciduous American Azaleas, was introduced from North America as far back as 1734, it was not until some forty or so years ago that some Continental cultivators took up the matter of hybridisation systematically, and thus we obtained the brilliant varieties known as Ghent Azaleas. Previous to that some variation had shown itself, but such variations were chiefly in the form of sports or natural crosses, through the varieties being grown together. Mr. Anthony Waterer states that a semi-double variety, named Maiden's Blush, has been in cultivation for many years, but it would appear that it is about ten or twelve years ago when double forms began to show themselves among the seedling American Azaleas raised at the Knaphill Nursery; and on the 24th instant, Mr. Waterer was able to exhibit more than a dozen large specimens in full bloom. That they represent a very valuable break cannot be doubted, and the flowers, as is usually the case with double forms, are much more persistent than those of the single varieties. When grown as decorative plants in the open air, they last much longer in bloom, which fact adds greatly to their value, and then what superb conservatory plants they make at this season of the year. They require but very little forcing; they simply want to be brought on in an ordinary house, so as to have them in flower before they can bloom in the open air. Those shown at South Kensington by no means exhausts all the varieties Mr. Anthony Waterer has; some have rose and scarlet hues, and they are very attractive. To two of them (*Snowflake*, pure white, and *Peach Blossom*, bright pink, with a blotch of orange on the top segment) first class certificates were awarded. These double forms produce but little seed, and many of the seedlings revert to the single form. The best method of propagation is by layers. But little pruning is required, as the marvellous freedom with which they bloom checks anything like exuberant growth. R. D.

The Labrador Tea, as *Ledum latifolium* is called, is a pretty little shrub that should be seen in well planted gardens at this season covered with dense clusters of white blossom. It is the more conspicuous in bloom just now, as there are not many counter attractions in the shrubbery, its more showy relatives, the *Rhododendrons*, *Azaleas*, and *Kalmias*, not being in bloom yet. It is one of the few flowering shrubs that will thrive in a perpetually moist and even swampy spot, and it often exercises one's memory to think of shrubs that one would like to plant in a damp spot, such as at the edge of a bog garden, or a place where water collects. All the *Ledums* are partial to a peaty soil, but they will grow in a loamy soil, if it be lightened with Moss or leaf-mould.—W. G.

Double flowering Cherries.—Wherever a selection of flowering trees is made, some of the Cherries must be included, and where there is not sufficient room for the full development of the larger kinds, there are some that will not soon outgrow the space allotted to them. Of such, mention may be made of the Chinese *Cerasus serrulata*, which forms a low tree or shrub, reaching a height of 8 feet or 10 feet, with stout wide-spreading branches and but few laterals, so that it is readily distinguished from any of the others at all seasons of the year. The blooms are semi-double, and when first expanded pure white, but before dropping they become somewhat tinged with pink. The specific name is derived from the edges of the leaves being distinctly toothed or serrated. *Cerasus Sieboldi alba plena* and *rosea plena* are two pretty shrubs, with respectively white and rose-coloured flowers. The habit of these two kinds is rather

drooping, and on that account they are usually grown as standards. The pretty little slender-growing *Cerasus* or *Prunus sinensis* is earlier than any of the others, and is very valuable as a spring-flowering shrub, either under glass or in the open ground. The flowers are like little white rosettes, and the slender twigs are thickly studded with them. As the finest of all the double-flowered Cherries the place of honour must be assigned to the double variety of *C. avium*. When seen in the shape of a good sized healthy tree, and laden with its drooping clusters of pure white blossoms it is a most magnificent object.—T.

SOCIETIES AND EXHIBITIONS.

CRYSTAL PALACE.

MAY 21.

THE great summer show, held on Saturday last, was remarkable both for the quantity and quality of the collections brought in response to a fairly well diversified schedule. The arrangement taken as a whole was very effective and pleasing, but from the manner in which the collections in the same class were scattered, it would not appear that much thought or care had been given to the convenience of the judges. It is, in our opinion, very unfair to the judges to have competing collections staged widely apart, as it is quite impossible for nice distinctions to be satisfactorily adjudicated upon when so arranged, and this must be accepted as an apology for any slight discrepancies which may have arisen upon the present occasion.

Stove and greenhouse plants, *Azaleas*, *Ericas*, *Roses*, and *Pelargoniums* were shown in considerable quantities in excellent condition, very many of them being the same plants which figured so conspicuously at the meeting of the Royal Botanic Society last week.

For a group of *Orchids* in bloom, not less than forty plants, arranged with a few *Palms* for effect, there was keen competition, the successful exhibitors being Mr. Simpkins, gardener to Mr. Measures, Cambridge Lodge, Camberwell; Mr. Salter, gardener to Mr. J. Southgate, Selborne; and Mr. Cooke, gardener to Mr. De B. Crawshay, Rosefield, Sevenoaks. Mr. Measures's group contained about two hundred *Orchids* in flower, comprising nearly eighty distinct kinds; the groundwork was composed of *Pteris serrulata*, and edged with *Maiden-hair Fern* (*Adiantum euneatum*), the whole being very tastefully arranged. The most notable plants in bloom were *Oncidium Marshallianum* and *concolor*, numerous well-flowered *Vandas*, *Masdevallia Harryana* of various shades of colour, grand varieties of *Cymbidium Lowianum*, quantities of *Cattleyas Mendeli* and *Mossie*, some of which were extra fine varieties; *Cattleyas Lawrenceana* and *Aelandia*, *Odontoglossums Alexandra*, *cirrhosum*, and *citrosimum*, *Cypripediums caudatum*, *Stonei*, *levigatum*, and *ciliolare*, *Coclogyne pandurata*, *Laelia purpurata*, numerous *Dendrobiums*, and a magnificent *D. Griffithianum*, &c. Mr. Salter followed with a very artistically arranged group, intermixed with *Ferns* and *Palms* and edged with *Maiden-hair Ferns*; it contained *Cattleyas Warneri*, *Mendeli*, *Mossie*, and the rare white form of *C. Skinneri*, *Saccolabiums*, *Aerides*, numerous *Dendrobiums* and *Oncidiums*, *Masdevallias Chimera*, *Shuttleworthi*, *Harryana*, and various others, *Odontoglossum nevium majus*, excellent varieties of *O. vexillarium*, the rare *O. polyanthum*, which appears to belong to the triumphans type, sepals and petals tawny orange-yellow spotted and blotched with chocolate, lip deep chocolate, with a white serrated edge; *Cymbidium Lowianum*, well flowered, an excellent variety, &c. Mr. Crawshay's plants were remarkable for their quality, but the group was not quite so large. The most notable were grand examples of *Laelia purpurata*, fine forms of *Cattleya Mossie* and *C. Mendeli*, several very fine *Odontoglossum Alexandra*, *Dendrobium Jamesianum*, *D. thyrsiflorum*, *Odontoglossums citrosimum* and *Uro-Skinneri*, &c. Very pretty groups were also contributed by Mr. Luff, gardener to Mr. R. Hyatt, Streatham, and Mr. James, nurseryman, Norwood.

Nine distinct Orchids in bloom brought collections from Mr. Catt, gardener to Mr. W. Cobb, Silverdale Lodge, Sydenham, Mr. Hill, gardener to Mr. Little, The Barons, Twickenham, and Mr. James, and these were placed in the order here given. Mr. Cobb's plants were of the highest merit; they were *Masdevallia Harryana Dawsoni*, with twenty flowers of large size and deep vermilion colour; *Odontoglossum Alexandra*, ten fine spikes; *Cattleya Mendeli*, a fine variety, bearing ten flowers; the superb *Cattleya Sanderiana*, three flowers; *C. Skinneri*, thirteen trusses; *Laelia purpurata*, twenty-two flowers; *Oncidium Marshallianum*, three large branching spikes; *Celogyne Massingiana*, two spikes; and a magnificent *Odontoglossum (Miltonia) vexillarium*, bearing about 200 flowers, well produced above the foliage. Fine as these plants were, however, they were closely pressed by those from Mr. Little, who sent a fine variety of *Cattleya Mossiae*, with twenty blooms; *Cypripedium caudatum roseum*, four flowers; *Aerides Fieldingi*, four spikes, not quite open; *Cattleya Mendeli*, a fine form, bearing fifteen flowers; *Odontoglossum hystrix*, four spikes; *Cattleya Skinneri*, eight trusses; *Dendrobium thysiflorum*, about twenty trusses; *Odontoglossum Pescatorei*, sixteen spikes; and a very fine variety of *Oncidium Marshallianum*, with two spikes.

In the amateurs' class for six Orchids the successful competitors were Mr. Catt, Mr. Hill, and Mr. Luff. Mr. Catt's plants were *Laelia purpurata*, *Oncidium Marshallianum*, *Odontoglossum vexillarium* and *Alexandra*, *Cypripedium niveum*, and *Aerides Fieldingi*. Mr. Hill's chief plants were *Cattleyas Mendeli* and *Mossiae*, *Dendrobium thysiflorum*, and *Cypripedium ciliolare*; whilst Mr. Luff staged *Vanda suavis*, *Cypripedium villosum*, *Odontoglossum vexillarium*, *Oncidium Marshallianum*, *Lycaste Skinneri*, and *Phalaenopsis amabilis*. Single specimen Orchids were well represented by Mr. James, who was first with a fine *Laelia purpurata*, bearing about three dozen flowers; Mr. Hill, with a fine *Cattleya Skinneri*; and Mr. Wakeham, gardener to Mr. H. Barratt, North Dulwich, who staged a very good *Cattleya Mossiae*.

In the class for a group of miscellaneous plants arranged for effect on a space not exceeding 200 square feet, Messrs. Laing and Co., nurserymen, Forest Hill, deservedly carried away the leading honours with a magnificent group of flowering and ornamental-leaved plants, massive, yet by no means heavy, the whole being very skilfully and artistically arranged. Its chief features were graceful Palms, Ferns, *Dracaenas*, *Aralias*, and highly coloured *Crotons*, numerous well-flowered Indian *Azaleas*, *Erietas*, *Orchids*, remarkably fine tuberous *Begonias*, for which this firm has obtained a world-wide reputation, &c., &c. Messrs. Hooper and Co., Covent Garden, and Pine-apple Nursery, Maida Vale, also staged a very effective group; its leading characteristic was similar to the last, whilst the border was composed of *Panicum variegatum* and *Isolepis gracilis* arranged alternately. Mr. James, of Norwood, also furnished a somewhat similar group.

In the class for *Nepenthes*, not less than twelve specimens, groups were staged by Mr. James, Norwood, and Mr. Luff, Streatham. These plants did not show to advantage, arranged as they were upon a flat stage in a dark corner. They should be set upon slender, tall pedestals, in order to display their beauties in a natural manner. The best in Mr. James's set were *N. Mastersiana*, several varieties, *Williamsi*, *Rafflesiana*, *Stewarti*, *Hookeri*, *Dominiana*, *Courti*, *Harryana*, *distillatoria*, *hybrida*, and *robusta*. Mr. Luff's were mostly similar varieties, in addition to *Morgani*, *Chelsoni*, and *anerleyensis*.

*Sarracenia*s were staged by Mr. Luff and Mr. James, but neither of the collections were sufficiently advanced in growth to give an idea of their singular beauties.

Messrs. Carter, Dunnett, and Beale, Forest Hill, exhibited a large group of *Mimulus*; these were remarkable for the size of the flowers, their rich colours, exquisite spotting and blotching, and also from their character of coming true from seed.

Messrs. Barr and Son staged a magnificent group of cut *Narcissi*, which they appear to have in any quantity in their celebrated bulb garden at Tooting.

Stove and greenhouse Ferns were staged by Mr. Penfold, gardener to the Rev. Canon Bridges, Beddington; Mr. Bolton, The Gardens, Coombe Bank, Sevenoaks; and Mr. James, Norwood. Mr. Penfold's plants were large, fresh, and well-grown specimens of *Davallia fijiensis*, *Mooreaana*, and *polyantha*; *Lastrea laserpitifolia*, *Lomaria cycadefolia*, *Dicksonia antarctica*, *Woodwardia radicans*, and *Microlepia hirta cristata*.

Dracaenas in the amateurs' class were both good and varied; the first prize for six distinct kinds was carried off by Mr. King, gardener to Mr. P. Crowley, Waddon House, Croydon, his best plants being *D. Lindenii*, *majestica*, *anerleyensis*, *amabilis*, and *recurva*.

Dracaenas, distinct (open), came from Messrs. James, Luff, and Hooper and Co., the best amongst which were *Lindenii*, *salmonea*, *elegantissima*, *anerleyensis*, *albo-marginata*, *imperialis*, *Goldiana*, and *Baptisti*.

Caladiums came from Mr. Laing, Forest Hill, amongst which were notable *Leopold Robert*, *luteum*, *Clio*, *Comtesse de Condeixa*, *Sanchonanthum*, *Luddemanni*, and *Mithridates*.

Gloxinias were well shown by Mr. Luff, who carried everything before him with a beautiful lot of erect, spotted kinds.

Calecolarias were numerous and good. The plants sent by Mr. James, of Farnham Royal, Slough, were remarkably dwarf in growth, whilst the flowers were abundant, large, and of good form, but were scarcely so well diversified in colour as Mr. Salter's, of Streatham.

Miscellaneous groups were staged by Messrs. Paul and Son, Cheshunt, and by Mr. Ware, of Tottenham, and contained many plants of great beauty and excellence, the majority of which we referred to in our columns of last Saturday as having been exhibited at the Royal Botanic Society's meeting.

Plants suitable for table decoration were very numerous, but not of great variety; no novelties were introduced, and they do not call for special notice.

Cut flowers were staged in profusion both in the open classes and those confined to amateurs, but the stands contained nothing particularly notable. For the best vase or epergne for drawing room, Mr. Phippen, of Reading, was first, and Mr. Chard, Stoke Newington, second, with which decision our opinion did not coincide. The former's exhibit was a stand with branches bearing three tiers of circular cups and a terminal one, six in the lower tier and three each in the upper ones. Each one had for the centre a small seedling *Cocos Weddelliana* surrounded with cut blooms of *Orchids*, *Rhodanthe*, *Marzuerites*, *Lily of the Valley*, *Selaginella*, and *Maiden-hair Ferns*, &c., the whole having a heavy and massive appearance, entirely lacking the grace and elegance of that of the one placed second.

Bouquets and button-hole bouquets were numerous. Few, however, were characterised by much taste, whilst some of the bouquets appeared as if the object the makers had in view was to pack the flowers together as tight as the head of a Cauliflower. Bridal bouquets were shown by Messrs. Perkins, of Coventry, Mr. Chard, Stoke Newington, and Mr. Phippen, Reading, Messrs. Perkins being first and Mr. Chard second. These two were composed of very similar flowers, viz. *Stephanotis*, *Tuberoses*, double *Primulas*, *Eucharis*, *Bouvardias*, &c. The former's bouquet appeared to be much too tightly packed, and the latter slightly overdone with Fern.

The following certificates were awarded: To Mr. Laing, for *Begonia Princess Victoria*, *B. Duke of Edinburgh*, and *Azalea Francois Verveine*; to Mr. Ware, for *Moutan Paeonies Urtica*, *odorata Maria*, *Louise Mouchet*, and *Rinzi*; to Mr. Wiggins, Kingston, for *Pelargonium Henry Dawkes*; and Mr.

Little, Twickenham, for *Laelia purpurata Mrs. H. Little*.

A prize list is given in our advertising columns.

ROYAL HORTICULTURAL.

MAY 24.

THE exhibits at this meeting were not numerous. The following first-class certificates were awarded:—

Azalea Maiden's Blush. A hardy form, flowers creamy pink, stained with yellow in the upper petals (Messrs. Veitch and Sons).

Azalea Beauty, rosy pink (Messrs. Veitch and Sons).

Azalea Peach Blossom, a semi-double flower, rosy peach (Mr. A. Waterer).

Azalea Snowflake, pure white, semi-double, very fragrant (Mr. A. Waterer).

Odontoglossum Pescatorei (Pollett's variety). A form with the sepals and petals beautifully spotted (Mr. J. M. Pollett).

Mimulus Carter's Jubilee Queen's Prize, large, beautifully spotted and blotched flowers (Messrs. Carter and Co.)

Phalaenopsis speciosa, rich bright violet-purple, flowers (Major-General E. S. Berkeley).

Paeonia Moutan Balmieri, rosy magenta (Veitch).

Paeonia Moutan Isis, clear bright carmine (Veitch).

Abies excelsa mutabilis, young growths clear yellow (Veitch).

Paeonia Moutan lactea, white (Ware).

Paeonia odorata Maria, large soft blush (Ware).

Paeonia Moutan Zenobia, magenta-carmine (Ware).

Ranunculus cortusefolius, a bold-growing species from Madeira, nearly a yard high, with bright shining yellow flowers about 2 inches across (Mr. E. G. Loder).

The great features of the show were the beautiful hardy plants staged by Messrs. Paul and Son, Cheshunt, and Mr. Ware, of Tottenham. In Messrs. Paul's group were *Saxifraga Lindisiana*, *Houstonia scryphillifolia*, blue, with yellow eye; *Phlox nivalis*, vivid, *divaricata alba* and *Nelsoni*, which is undoubtedly the best white; a large mass of the rich blue *Gentiana acaulis*, and the smaller, but exquisite, *G. bavarica*; *Trillium grandiflorum*, flowers large, pure white; a large mass of the Prophet Flower (*Anemba echinoides*); *Lithospermum prostratum*; the red and buff-flowered *Orobanchium*; the lovely *Tiarella cordifolia*, with white *Spiraea*-like trusses of flowers; *Epinediums niveum* and *Kariso*; *Geum aureum*, with clear golden yellow flowers; and *G. miniatum*, orange-red; *Thalictrum anemoides*, with snow-white single flowers; its double counterpart, *anemoides plenum*; and *aquilegifolium rubrum*—the flowers, however, though beautiful, are nearer lilac than red. Poppies were represented by *nudicaule croceum*, large, rich golden yellow, and the orange red *miniatum*; *Anemone sulphurea*, with large, pale yellow flowers; *A. nemorosa plena*, dwarf, with large, snow-white double blooms; *Kalmia glauca*, *Veronica repens*, *Iberis jucunda*, *Primula Munroi*, delicate creamy white; *Ranunculus graminis*, *Androsace sarmentosa*, and *Trollius napellifolius*, its rich golden balls of flowers being very conspicuous.

Mr. Ware, Tottenham, staged a large group of *Moutan Paeonies*, bearing large flowers of rich and varied colours. This is a class that should be largely grown, as they have a beauty peculiarly their own. The alpine and herbaceous group comprised a grand mass of *Trillium grandiflorum* with extra large white flowers, numerous forms of the Japan Primrose (*P. Sieboldii*), *Cypripedium Calceolus*, *C. occidentale*, the curious *C. arictinum* and *C. pubescens*, *Orchis mascula*, various *Trollius*, &c.

Messrs. Veitch and Son, Chelsea, staged a group of *Spiraea confusa* profusely laden with corymbose heads of snowy flowers; this would appear to be an invaluable plant for forcing; a basketful of the lovely Japan *Azalea roseo-flora*, and *Abies excelsa mutabilis*, a form in which all the young shoots are bright yellow, contrasting beautifully with the deep green

of the old growths; several plants of hybrid hardy Azaleas, crosses between *A. mollis* and *occidentalis*, densely laden with large trusses of creamy rose flowers, having a stain of orange-yellow on the upper petals. A group of *Hydrangea stellata* fl.-pl., very dwarf plants, each bearing a large truss of bright pink flowers; the curious *Illicium floridanum*, with cinnamon-red double flowers; *Rosa lucida* Rose Button, very floriferous, lovely in bud; a double form of *Lilae* called *Lemoinei* fl.-pl., and numerous Mountan Paeonies, amongst which were *P. Isis*, clear bright carmine; *P. rosea superba*, bright scarlet; *P. Grand Duc de Bude*, rosy mauve and purple with feather-edged petals; *P. Caroline*, creamy pink; *P. Baineri*, rosy magenta, and *P. Urani*, deep rose. Some hardy hybrid Azaleas were sent by Mr. C. Vuytsteke, Ghent.

ORCHIDS.—Mr. Pollett, Fernside, Bickley, sent a beautiful spotted form of *Odontoglossum Pescatorei*. Mr. Philbrick sent *Hexisea bidentata*, a curious *Dendrobium*-like plant with somewhat small cinnamon-coloured flowers. Major-General E. S. Berkeley sent *Phalaenopsis speciosa Ludlemanniana*, the flowers wholly rich violet.

Mr. Loder, Floore, Weedon, sent three fine specimens of the Chatham Island Forget-me-not (*Myosotidium nobile*) bearing numerous trusses of its lovely blue flowers; and *Ranunculus cortusae-folius*, a gigantic species from Madeira, nearly a yard high, and bearing numerous large shining, bright yellow flowers. It is said not to be hardy at Floore.

Mr. A. Waterer sent three specimens of hybrid Azaleas of the mollis section bearing large, highly-coloured flowers; and also a group of his seedling double *Azalea occidentalis*.

Messrs. Wood and Ingram, Huntingdon, sent *Pelargonium J. Wood Ingram*, belonging to the show decorative class, very free-flowering; flowers intense fiery red; lower petals clear, upper ones heavily blotched with velvety black.

Mr. R. Dean, Ealing, sent *Polyanthuses Governor and Snowdrop* in fine condition from the open ground, and a dwarf strain of *Cineraria* called *Royal Blue*. The plants were said to have been wintered without fire-heat.

Messrs. Carter, Dunnett, and Beale staged fine groups of their *Mimulus Jubilee Queen's Prize*, *M. Princess Victoria*, and *M. Princess Beatrice*, bearing large magnificent flowers.

From the Society's Gardens, Chiswick, came a well-flowered plant of the old, but beautiful *Tropaeolum azureum*.

Fruit committee.—The labours of the committee on this occasion were very light.

Pears were exhibited by Mr. G. Beaton, The Gardens, Style Hall, Gunnersbury. They comprised *Vicar of Winkfield*, *Easter Bauré*, and *Suzette de Bayay*.

Mr. W. H. Hume Dick, Thames Ditton, sent a dish of very fine Asparagus, also a dish of Strawberry Anguste Nicaise, good in size and well coloured, for which he received a cultural commendation.

Mr. E. Ward, Stoke Edith, Ledbury Park, sent samples of good Broccoli.

Mr. Lockie, The Gardens, Oakley Court, Windsor, sent six fruits of a seedling Melon called *Beauty of Windsor*, the result of a cross between Dr. Hogg and *Victory of Bath*. It is a very handsome netted fruit.

Messrs. Sutton and Sons' prizes for Cucumbers were competed for on this occasion. Mr. Lockie, The Gardens, Oakley Court, Windsor, was first with a magnificent brace of Sutton's Improved Telegraph, measuring 21 inches in length; Mr. Waite, Glenhurst Gardens, Esher, second with a brace of Sutton's Purley Park Hero; and Mr. Downing, The Shrubbery, Enfield, third with Sutton's Improved Telegraph. Colonel Lee, Hartwell House, Aylesbury, Mr. Haines, The Gardens, Coleshill House, Highworth, and Mr. Kitching, Lauriside, Malvern, were the other exhibitors.

Scientific Committee.

Peristeria sp.—Mr. Ridley reported on the two forms exhibited at the last meeting, having discovered no trace of sexual difference, the colouring of the two supposed species being scarcely specific in character.

Plants exhibited (*Astelma eximium*).—Dr. Low exhibited specimens of this Everlasting, received from Lady Frere, and brought from South Africa. It was introduced into England in 1793 and figured *Botanical Register* (tab. 582), and the *Journal of Horticulture* (p. 233, March 24, 1881).

Ceratopogon pallidum.—Shown by Mr. Smee. It had been accidentally imported with Orchids from the Himalayas.

Ranunculus cortusae-folius.—A fine plant nearly 3 feet in height was sent by Mr. Loder. It is a native of the Canary Islands and Madeira (*Botanical Magazine*, t. 1625). It is said to be hardy, but has not proved to be so at Floore, Weedon. It was remarkable not only for the large size of the golden yellow flowers, more than 2 inches across, but from the seemingly total absence of the honey-glands at the base of the petals.

Cypripedium arcticum.—Mr. Ware sent a plant of this curious Orchid, figured in the *Botanical Magazine* in the year 1813 (tab. 1569). It is characterized by the anterior pair of sepals being free instead of coherent, as in most species.

Moustrous flowers.—*Calceolaria*, double, with the "slipper" repeated, sent by Mr. Veitch, and *Primroses* with foliaceous sepals free and coherent, also partially coloured, &c., forwarded by Mr. A. Dean.

LAW.

PURSER V. THE WORTHING LOCAL BOARD. (Before the MASTER OF THE ROLLS, LORD JUSTICE FRY, and LORD JUSTICE LOPES.)

THIS case raised the question whether glasshouses and greenhouses, in which fruit, flowers, and vegetables are grown in the way of a man's trade for market, are to be assessed at their full net annual value, or only at one-fourth thereof under sec. 211, sub-sec. 1 (b) of the Public Health Act, 1875, which provides, *inter alia*, that "the occupier of land used as market gardens or nursery grounds shall be assessed in respect of the same in the proportion of one-fourth part only of the net annual value thereof." George Purser was a grower of fruit, vegetables, and flowers, carrying on business at Worthing, and describing himself as a "market gardener and nurseryman," and he occupied a piece of land about 1a. 1r. in extent, upon which were sixteen glasshouses or greenhouses of various sizes, substantially built, and used by him for the purpose of growing Tomatoes, Cucumbers, Grapes, flowers, &c., in the course of his business. The Local Board rated him in respect of the glasshouses or greenhouses on their full net annual value. The Divisional Court (Mr. Justice Day and Mr. Justice Wills) held that the land covered with glass was a "market garden" within sec. 211, sub-sec. 1 (b) of the Public Health Act, 1875, and the occupier was only liable to be rated at one-fourth of the full net annual value. The defendants appealed.

Mr. Lumley Smith, Q.C., and Mr. English Harrison, for the defendants, contended that the glasshouses, which were substantially built, with brick walls let into the ground, ought to be rated as buildings at their full net annual value, and were only adjuncts to and not part of the market garden.

The Court yesterday dismissed the appeal. The Master of the Rolls said that the case was a clear one. This land was not used as a pleasure garden, but as a market garden. It was used for the purpose of utilising the soil to grow vegetables and other things which the market gardener sold in the way of his business. Was it the less "land used as a market garden" because it was covered with glass? Certainly not. That in reality was the whole case.

The Lords Justices concurred.—*Times*.

Gardeners' Orphanage Fund.—A meeting of the provisional committee was held at South Kensington on Tuesday last. Donations and subscriptions to the amount of £568 11s. were announced, and the following resolution unanimously adopted: "That the provisional committee is of opinion that the progress made is sufficiently satisfactory to warrant the calling of a general meeting to establish the same, and that such meeting be held on the 12th of July."

Opening of Richmond Terrace Gardens.—The Duke of Buccleuch having determined to sell his estate lying between the top of Richmond Hill and the river Thames, the inhabitants resolved to obtain this, and, with the sanction of the Local Government Board, purchased the property for £30,000. Last Saturday the upper portion of the grounds attached to Buccleuch House was opened by the Princess Mary of Teck as a place of recreation for the inhabitants.

We are informed that, through the kindness of Mr. A. H. Smee, any of our readers who care to come during next week may inspect his garden (the Grange, Hackbridge, Carshalton, Surrey). There are many fine forms of *Cattleya Mossie* at present in flower.

Royal Horticultural Society.—We learn that the council of this society have resolved to call a special meeting of the Fellows to be held at South Kensington on June 28, to take into consideration the present state of the society with a view to future arrangements.

Destruction of rabbits.—Can any of your correspondents suggest some way for the wholesale destruction of rabbits? Can they be poisoned or smoked out of the burrows? Here they are simply vermin.—S. W. F.

BOOKS RECEIVED.

"The Fungus-Hunter's Guide and Field Memorandum Book." By W. Delisle Hay. Swan, Sonnenschein, Lowrey and Co., Paternoster Square.
"Gleanings in Old Garden Literature." By W. Carew Hazitt. Elliott Stock, 62, Paternoster Row.

Names of plants.—*T. J.*—Cannot name varieties of *Gloxinias*.—*B. B.*—1, *Asplenium pumilum*; 2, *A. Belangeri*; 3, *Doodia aspera*; 4, *Adiantum concinnum latum*.—*H. S.*—1, *Pulmonaria angustifolia*; 2, *Allium* sp.; cannot name unless we have flowers.—*H. Church.*—1, *Beberis barbinis*; 2, *Genista virgata*; 3, *Prisylhia viridissima*; 4, *Ribes aurea*.—*F. A. St. m.*—1, *Rhodiola minor*; 2, *Spiraea prunifolia*.—*P. Davidson.*—Your plant is *Polygala vulgaris*.

WOODS & FORESTS.

"YORKSHIREMAN."

THE NOOTKA SOUND CYPRESS.

(CYPRESSUS NUTKAENSIS.)

AT the late Colonial and Indian Exhibition one of the largest and most conspicuous samples of wood was a clean and well-polished specimen of the above tree, which clearly set forth the beautiful graining as well as large size to which it attains in its Canadian wilds. The specimen under notice was no less than 18 feet in length, 1 foot in width, and 2 inches thick, clean, smooth, and knotless as a piece of Yellow Pine, and as prettily grained and of as desirable a colour as could well be desired even by the most fastidious of wood-fanciers. To Professor Macoun, of Ottawa, I am indebted for a great deal of information regarding this and others of the Canadian woods, apart altogether from their value in a commercial sense and quality of timber, this latter being fully set forth in the exhibited specimens both of a manufactured and unmanufactured type.

The timber, which is of a pale yellow colour, is remarkably light, tough, close-grained, and durable, susceptible of a high polish, and has a pleasant fragrance not unlike that of Sandal-wood, this latter being retained unimpaired for many years; for we are informed that on cutting into the fallen trees of the woodland where they have lain for upwards of a century, the heart-wood is quite fresh and the pleasant fragrance distinctly detectable. The fragrance of the wood has caused it to be extensively used, particularly by the Chinese, in the manufacture of workboxes and fancy articles of many kinds.

Boats and canoes are likewise made of the timber of this Cypress, and have proved lasting and strong; while oars, paddles, furniture, fencing materials, wagons, and household utensils are but a few of the many uses to which it is applied.

How indestructible the timber is may be inferred from the fact that blown-over trees are frequently found in their native woods almost perfectly sound after the lapse of half a century and more, this being quite evident from the number of seedlings that have sprung up and attained to large size close beside the prostrate stems—nay, even in some instances on the very backs of their ancestors. The decaying leaves and branches soon envelop portions of the fallen stems, thus, combined with their Moss-covered bark, affording an excellent bed for the tiny seed.

Here, then, we have in one of the most valuable timber-producing Cypresses a tree that is peculiarly well adapted for cultivation in this country—a statement that requires nothing to back it up, save, indeed, a glance at the numerous fine trees to be met with in almost every collection throughout Britain. It is, indeed, not a tree of very rapid growth, but it makes up for this in its stout, well-formed stems and perfect immunity from harm, even during our most severe and long-continued winters. Rarely, indeed, is it that one hears of this Cypress having suffered from the inclemency of the weather, although it has been largely planted in all situations and exposures both in Scotland, England, and Ireland. A leader is rarely injured or a tree upturned during our most severe storms, so hardy and sturdy is this valuable Cypress. As regards choice of soil, I certainly know of no Cypress that is less particular, for we have it growing luxuriantly in all the intermediate gradations between gravel and clay. Even in reclaimed peat it forms a handsome, portly tree; indeed, the prettiest and fastest growing specimens I can at present remember are growing where peats for fuel were at one time obtained, but which now by draining, &c., is reclaimed into as good a soil for Conifers generally as one need wish to possess. Shingly, broken-up rock also produces excellent examples of the tree in question, the roots seeming to delight to wander amongst such, but particularly so where an excessive amount of moisture is present. Stiffish, but strong loam will also be found well suited for the wants of this tree, the finest specimen on this estate being planted in such. The largest tree I have seen measures 42 feet in

height, has a stem girth of 4 feet 11 inches, a spread of branches covering a diameter of fully 18 feet, is well clothed to the very ground level with an abundance of glossy foliage, and is growing in a kindly sandy loam, and at no great altitude above sea level. How long this tree has been planted I am unfortunately unable to say, but others of twenty years' growth are about 18 feet in height, and in the nursery four-year-old plants are a yard in height.

Generally speaking, under favourable circumstances and when the tree is perfectly established, the rate of growth upwards is about from 7 inches to 9 inches—rarely more than the latter—per year, but the growth produced is strong, elastic, and well matured. The increase of thickness in the lower portion of the stem of fair-sized trees of this Cypress is very observable, that for 6 feet from the ground being greatly in advance of that further up. In other words, the taper in the stem is considerable, more so than in the Cypress tribe generally.

In the nursery the propagation and management of this Cypress is of the simplest description, it being readily increased either from seeds or by inserting cuttings in sharp sandy soil during the latter end of August. The latter is the usual method of propagation, but, in our own opinion, an inferior way to raising from seeds, the produce of the latter seeming to start away with greater freedom than plants raised from cuttings. In raising this Cypress from cuttings these should always be chosen from the most robust-growing specimens, there being a dwarfish close-habited plant and a far more desirable form with an open spreading habit and more tree-like appearance in circulation. The typical *Cypressus nutkaensis* is a fine, spreading-branched tree, with a great exterior resemblance to *C. Lawsoniana*, but, we think, an inferior plant to that well-known species, in ornamental appearance at least. It is more stiff and rigid in outline than the Lawson Cypress, and wanting to a very great extent in the long weeping branchlets that are so characteristic of well-grown specimens of that plant. Usually the branches have an upright tendency, with numerous drooping branchlets thickly clothed with small, closely imbricated, sharp-pointed leaves, of a rich dark green above and slightly glaucous on the under side. The cones are produced in great abundance even on the lower branches, are about the size of a good large Pea, and contain usually two dozen seeds each.

There is a beautiful golden form of this Cypress which is far more ornamental than the typical plant, the tips of the branchlets being of a light and pleasant yellow colour. By far the finest specimen of this variety I have seen is growing on the lawn at Penrhyn, it being nearly 30 feet in height, with a spread of branches 18 feet in diameter, and a stem girthing 3 feet 2 inches at a short distance from the ground. It is undoubtedly the most distinct and ornamental Cypress I know of, the long, drooping branchlets hanging limp and easy for, in some instances, 30 inches in length. This is not the form that is usually sold by nurserymen under the name of *C. nutkaensis aureo-variegata*, for this latter differs nothing from the type except in the golden-tipped foliage, whereas in the specimen under notice the branchlets are lengthened to four times their usual size. I have never seen a tree at all approaching the Penrhyn one, and several 'cute tree-lovers to whom I have pointed it out declare that it is perfectly distinct from anything else at present known. Not a dozen feet from it is a fine specimen of the normal plant, placed, one might suppose, so as to show the great difference between it and its handsomer and far more desirable variety—if variety it be.

A. D. WEBSTER.

Mismanaged planting.—In reply to "Yorkshireman" in your issue of May 21 (p. 479), did ever "Rusticus" see a timber tree without a tap root, unless injured by transplanting? I beg to call "Yorkshireman's" attention to the Wych Elm, *Ulmus montana*; the English Elm, *Ulmus campestris*; the Lime Tree, *Tilia europæa*, the two latter generally being raised by layers. How does "Yorkshireman"

account for tap roots being on these trees, or has he ever seen them with them? If he has, he must have some other way of distinguishing a tap root from any other root than what the writer has. I have had occasion this last season to plant several thousand trees (Oak) from a public nursery. I fail to see the object of a bare tap root that has to be planted out in the woodland. Give me the plants that have been frequently transplanted with plenty of fibrous roots.—RUSTICUS.

THE PRESERVATION OF WOOD.

THE durability of wood—that is, its power of resisting the destructive influences of wind and weather—varies greatly, and depends as much upon the particular kind of wood and the influences to which it is exposed as upon the origin of the wood (timber), its age at the time of felling, and other conditions. Beech wood and Oak placed permanently under water may last for centuries. Alder wood lasts only a short time when in a dry situation; but, when kept under water, it is a very lasting and substantial wood. Taking into consideration the different kinds and varying properties of wood, and the different uses to which it is applied, we have to consider, as regards its durability, the following particulars: 1. Whether it is more liable to decay by exposure to open air or when placed in damp situations. 2. Whether it is, when left dry, more or less attacked by the ravages of insects, which, while in a state of larvæ, live in and on wood. Pure woody fibre by itself is only very slightly affected by the destructive influences of wind and weather. When we observe that wood decays, that decay arises from the presence of substances in the wood which are foreign to the woody fibre, but are present in the juices of the wood while growing, and consists chiefly of albuminous matter which, when beginning to decay, also causes the destruction of the other constituents of the wood; but these changes occur in various kinds of wood only after a shorter or longer lapse of time; indeed, wood may in some instances last for several centuries and remain thoroughly sound; thus, the roof of Westminster Hall was built about 1090. Since resinous woods resist the action of damp and moisture for a long time, they generally last a considerable time; next in respect of durability follow such kinds of wood as are very hard and compact, and contain at the same time some substance which—like tannic acid—to some extent counteracts decay. The behaviour of the several woods under water differs greatly. Some woods are after a time converted into a pulpy mass. Other kinds of wood, again, undergo no change at all while under water—as, for instance, Oak, Alder, and Fir. Insects chiefly attack dry wood only. Splint wood is more liable to such attack than hard wood; while splint of Oak wood is rather readily attacked by insects, the hard wood (inner or fully developed wood) is seldom so affected. Elm, Aspen, and all resinous woods are very seldom attacked by insects. Young wood, which is full of sap and left with the bark on, soon becomes quite worm-eaten, especially so the Alder, Birch, Willow, and Beech. The longer or shorter duration of wood depends more or less upon the following: *a.* The conditions of growth. Wood from cold climates is generally more durable than that grown in warm climates. A poor soil produces as a rule a more durable and more compact wood than does a soil rich in humus, and therefore containing also much moisture. *b.* The conditions in which the wood is placed greatly influence its duration. The warmer and moister the climate the more rapidly decomposition sets in; while a dry, cold climate materially aids the preservation of wood. *c.* The time of felling is of importance; wood cut down in winter is considered more durable than that felled in summer. In many countries the forest laws enjoin the felling of trees only between November 15 and February 15. Wood employed for building, and not exposed to heat or moisture, is only likely to suffer from the ravages of insects; but if it is placed so that no draught of fresh air can reach it, to prevent accumulation of products of decomposition, decay soon sets in, and the decaying albuminous substances acting upon the fibre cause it to lose its tenacity and become a friable mass. X.

No. 811. SATURDAY, June 4, 1887. Vol. XXXI.

"This is an Art
Which does mend Nature: change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

FLOWERS IN THE HOUSE AND EDITOR'S TABLE.

Under this head we propose, during the present season of flowers, to notice things, from whatever department, that are pretty and useful for the house. Any reader who will help us by sending fitting things, or a word about them, will oblige. The simplest things from the smallest garden, and even from the woods and fields, need not be excluded.

WHITE WOOD LILY (*Trillium grandiflorum*).—Flowers with leaves of this gathered fourteen days ago are still as fresh as the day they were gathered. This proves its high value as a flower for the house.

THE SNOWDROP ANEMONE (*A. sylvestris*) always comes in so well after the Wood Anemone, that it deserves to be in every garden, though in some soils it does not flower well. It has a slight fragrance. From Mr. Kingsmill.

THE ENGLISH LADY'S SLIPPER (*Cypripedium Calceolus*).—A very beautiful form of this from Mr. Kingsmill. It is prettier with its dark chocolate and lemon flowers than most of the tropical sorts.

PEARL BUSH (*Exochorda grandiflora*).—The prettiest thing now in the garden is a bush of *Exochorda grandiflora*, with its lovely white half pendent racemes. It is charming in a vase, especially with blue Gentians.—T. W. G.

HONEYSUCKLE.—A bowl of the earliest Honeysuckle; a most welcome house flower. A pale buff kind, very free flowering; the flower in pyramid-shaped tiers of bloom, set in a great, round, leafy collar.—J.

SNOWDROP ANEMONE (*A. sylvestris*).—A good handful of this, with its leaves, and a few of the longer-stalked alpine Anemone make a very pretty bouquet with a few sprays of young ivy leaves, now at their brightest and glossiest.—J.

PARROT TULIPS.—For a bold arrangement of strong colouring, few flowers give so gorgeous an effect, and they twist and tumble about in a way that helps their manipulator to dispose them in natural-looking, informal groupings.—J.

LEOPARD'S-BANE.—*Doronicum Harpur-Crewe* is a grand flower for cutting of much endurance, good both by day and night. A bold bunch cut with long stalks looks well with Laurel branches of a pale yellow-green colour.—J.

THE GARLAND FLOWER (*Daphne Cneorum*).—The alpine garden sometimes offers its bouquet of modest dimensions. The Garland Flower, with its rosy blooms and crimson buds, a few flowers of the pure white *Primula Munroi*, and newly-developed fronds of Oak Fern make up a little bunch of singular beauty.—J.

YELLOW WALLFLOWERS.—A big patch of these close under one's eyes is perhaps not quite acceptable; indeed, a big mass of any striking colour presents usually the same objectionable

features. But when, as I see here, a large mass of rich yellow Wallflowers 40 yards off and seen forming a background of gold beneath and beyond the trees which break the view, and more remote a patch still of purple Honesty, I find then something which is beautiful and meriting the designation of a picture.—A.

INDIAN AZALEAS FROM CORNWALL.—We have grand masses of this in the grounds quite 12 feet over. They have never flowered better, though they have had to contend against 18° of frost during the winter.—SANGUINEA.

PRIMULA OBOVATA.—I send a few sprays of *Primula obovata*, taken from a plant, of which we have many, that have stood out quite unprotected through the past severe winter.—SANGUINEA, Cornwall.

HABROTHAMNUS FASCICULATUS.—I have sent you much finer branches of this before. The present is only to show you how it has behaved outdoors through the severe frosts it has been subjected to.—SANGUINEA.

** Brilliant flowers—better than we have seen indoors.—ED.

LILIES OF THE VALLEY.—The famous growers of these, Messrs. Hawkins and Bennett, bring us a beautiful bunch of their Lilies of the Valley, so well known now in Covent Garden, and of which they occasionally send 500 bunches to the market in one day. The kind they grow is known as Hawkins' Victoria, but we think that it is by good cultivation that the beautiful flowers they bring us are produced. But there are certainly distinct forms of the plant.

PRIMULA SIEBOLDI.—I send you with this a few *Primula Sieboldi* blooms (the foliage is very handsome) to show how well they have stood these very heavy hailstorms, eight years in one spot without protection of any kind! Also, *Aquilegia viridiflora*, because it is an old favourite of yours. Sweet-scented, and an absolutely hardy perennial.—A. KINGSMILL.

AURICULAS.—The border kinds are capital cutting flowers, lasting long in water. The colours are so various that they should be classed together in different bouquets, as crimson and dark maroons together; purples, self and shaded, with whites and greys, and so on. If beds of seedlings are grown, there are sure to be some worthless ones whose whole crowns can be cut for foliage; no other leaves suit them so well.—J.

THE FIRE BUSH (*Embothrium*).—Brilliant specimens of this from "Sanguinea," who writes: "There are many fine plants in this neighbourhood at present one blaze of flower. I never saw them so grand before. There are plenty of plants in Cornwall over 20 feet high."

** The most brilliant thing we have ever seen on a tree.—ED.

TUFTED PANSIES FROM EDINBURGH.—I send you some Pansies given to me at Pirig Park Nursery to-day. Scotland is certainly the home of Pansies and Violas. I also send an Indian *Vaccinium* and a seedling Sycamore from the same nursery. The latter plant keeps its light colour all through the season, and seems an effective variety. *Fritillaria recurva* is also enclosed. I wish I had added a spray of *Asparagus giganteus*, the long wreaths and rapid growth of which must make it a valuable climb-

ing plant for conservatories, and perhaps in the south for outdoor culture as well. I intend to try it out of doors in Ireland.—C. M. OWEN.

** Delightful tufted Pansies, extremely delicate and pretty in colour, some of which we regret we do not know the names of. We believe these flowers, taken altogether, have more good qualities than any grown in our open gardens. Their hardiness and their value for the spring and summer garden, and as flowers for the house are equalled by nothing we know.

THE VINE-LEAVED INDIAN MALLOW (*Abrutilon vitifolium album*).—I send you a spray of this. It is a shrub of great beauty, and apparently quite hardy in Devonshire. This plant is trained, about 12 feet in height by 6 feet, and it is covered with hundreds of flowers and buds. I have had a smaller plant on the open border as a standard all the winter, and it is unharmed by frost.—T. H. ARCHER-HIND, South Devon.

** Flowers large and of the purest white.—ED.

THE CAUCASIAN SCARLET POPPY (*Papaver umbrosum*).—This gloriously coloured Poppy is so hardy, that it defies all weathers. A mass of autumn-sown plants now rich in its first blooms is so beautiful as to command admiration. The intense crimson hue of the flowers is admirably contrasted with the black blotches at the base of the petals, and conjointly moderates the glare which otherwise might be felt when looked upon closely. Why does not someone of our public gardeners treat the London public to a mass of this Poppy in the spring? If sown in September the plants will transplant admirably in November, and give the bed a covering of green foliage all the winter and a wondrous glow of colour in the spring.—A.

THE WHITE MALLOW.—How much all who see the big clumps of the paper-white *Malva moschata* even now become desirous of possessing plants. I regard it as a valuable addition to our hardy border plants, if for its beautiful cut foliage only. Weather seems incapable of harming it, and all the winter the foliage is green and vigorous. Gradually the shoots ascend, but remain even when 15 inches high clothed densely with foliage, and at 2 feet in height will be in good bloom. Those who specially love white flowers, whether in single clumps or in big masses, should have this charming Mallow. It comes readily from seed, which should be sown at once, and it is a very hardy perennial.—A.

BEAUTIFUL CLIMBERS.—I have sent you a gathering of flowers from our stove. The *Bougainvillea* is grand. I have two plants planted out on the glass end of a span-roofed stove. I planted them there and trained them over the end to give a little shade, and it has thoroughly answered the purpose. It is now one mass of flower—quite a sight. The *Stephanotis* is also planted out at the other end and trained over one side, and it is also one mass of bloom. It has been in flower fully three weeks now. The *Dipladenia Beareleyana* and *Clerodendron Balfourii* are planted out on the other side, and are blooming very freely over the roof. I have two *Allamandas* in tubs, *nobilis* and *Hendersoni*, in the centre, their branches growing at will, and they look quite at home. There is a fine lot of *Gloxinias* in flower; also *Gardenias*, double *Primulas*, &c., and a few *Orchids*, with *Caladiums*, *Draenas*, *Acalyphas*, *Fittonias*, and *Coleuses*, &c., and the remainder made up with Maiden-hair and other Ferns. Altogether it has a very gay appearance, and is most en-

joyable.—E. E. UNDERDOWN, *The Gardens, Colchays, Bovey Tracey, Devon.*

* * * The darkness of a London 1st of June was dispelled for us by receiving the above lovely wreath of stove climbers from Devon.—ED.

RHODODENDRON NUTTALLI.—We send you a truss of *Rhododendron Nuttalli*. This is the first time we have succeeded in flowering this superb plant. It is, we think, the best of the whole genus; in a truss were seven large funnel-shaped flowers, each 6 inches to 7 inches in length. The buds open a deep straw, which gradually changes to pale delicate straw colour. Our plant has been growing in the open air some years. Last autumn we fixed a frame overhead; probably this prevented the buds from being injured during the winter.—CHAS. SMITH AND SON, *Guernsey.*

— I send you a cluster of *Rhododendron Nuttalli*, the smallest of eight such clusters. Several blooms have measured from 5½ inches to 6 inches in diameter. How seldom this is seen in private gardens. I cannot call to mind just now one other garden where it is to be seen. It is a great pity, as when not in bloom, its noble foliage gives it a grand appearance. The plant from which this truss has been cut is growing in an 18-inch pot.—JOHN EASTER, *The Gardens, Rathlauric, Monasterivan, Ireland.*

* * * A plant of it may now be seen in flower in the temperate house at Kew.—ED.

ROSE GARDEN.

T. W. GIRDLESTONE.

ROSE PESTS.

Now that a little growth is at last visible upon the Roses, grubs and caterpillars are energetically to the fore, and must be zealously watched for and picked off. These troublesome visitors seem to be unusually numerous this year, and are liable to be especially mischievous in consequence of the backward state of the plants. When a young caterpillar elects to lunch off a more or less developed Rose leaf, even if he be overlooked for a day or two, no greater harm will have been done than the partial disfigurement of a leaf or two; but when, for lack of leaves, the caterpillar is boarded out on a young Rose shoot only an inch or less long, then, in addition to being out of sight, and so more difficult to find and much more difficult to kill without injuring the growth, it is impossible even for the best intentioned caterpillar to subsist without preying upon the vital parts of the shoot, and so destroying the chance of bloom therefrom.

The most obvious indication of the presence of grubs on a plant before the leaves are expanded is the curved position assumed by the young shoots, the curvature being caused by one side of the shootlet having been eaten away, so that its growth is retarded, while the uninjured side grows on in the normal way. The only thing to be done is to hunt diligently for the depredator's lurking-place, and then, carefully separating the still closely packed leaves of the shootlet, to extract as best may be and with as little breakage as possible the tiny creature that is working so much destruction. It is about this time of year, when it is necessary constantly to examine each plant, that growers are liable to point out the advantages of growing standards, just as the flies are said to have converted an uncompromising budler into an advocate of Roses on their own roots. Certainly if there be one branch of gardening more

than another that requires "a cast-iron back with a hinge on it," it is the culture of dwarf Roses, for whether the operation of the moment be budding, tying, suckering, pruning, grub-hunting, or aphid-killing, one is always—like a certain celebrated heroine—in a peculiarly doubled-up position.

Aphides are not yet in evidence, and their presence can very well be spared. The conditions of the season so far bear considerable resemblance to those of last spring, when, it will be remembered, there were but few complaints of aphid; but a terrible infliction of red rust, or orange-fungus, was very general, and if a similarity of season should again keep the Roses free from aphid, the same influences may also again involve a visitation of the former more unsightly pest, of which indications already are not wanting in certain quarters. Unfortunately, no satisfactory means of destroying orange-fungus has yet been found; the only thing to be done is to pick off the affected leaves, but then the remedy is almost worse than the disease, and is seldom effective in preventing the spread of the complaint among the denuded plants.

Mildew also has not so far made its appearance, but if it does so, the best thing to check it is to syringe the plants with a solution of sulphide of potassium at the rate of half an ounce of sulphide to a gallon of water. In addition to being far more effective, this process is also much less unsightly than that of dusting the plants over with dry sulphur, and the solution is easier to mix than either paraffin or soft soap. It is worth noting that the finer the spray in which the solution is thrown on to the plants the better, as it then adheres more readily to the foliage, and at the same time economises the fluid.

The best pillar Roses.—I should say most decidedly the best pillar Roses are the Hybrid China and the Bourbon varieties. They are not only profuse bloomers, but vigorous growers also, and they make shoots generally from 6 ft. to 10 ft. long every season, and their branches are flexible as well as vigorous; the flowers also are large and of very fine form in most instances. Then they are perfectly hardy and require but little pruning, and to do them full justice they should be planted in rich soil. In pruning, the wood should not be shortened, but simply the old and worn-out shoots cut right back to the main stem, leaving the young ones of the previous summer to bloom. Growers say that the best flowers are produced on two-year-old wood. A few of the best in this section are Charles Lawson, vivid rose, large and full; Coupe d'Hebé, rich deep pink, large and very double; Juno, pale rose; Paul Ricaut, bright rosy crimson; Paul Verdier, bright rose, large and full; and Souvenir de Pierre Dupuy, deep velvety red, very large and striking. I may add that the Tea-scented William Allen Richardson makes an excellent pillar Rose, and is being largely propagated by some of our leading nurserymen, as it is in demand for this purpose.—R. D.

Rosa berberifolia. Mr. Ewbank is asking for information about this Rose. I am afraid he will not extract much comfort from the following description taken from Edwards' *Botanical Register* for 1829 (tab. 1261), where it is figured under the generic name of *Lewea*, and described by Professor J. Lindley:—

This plant resists cultivation in a remarkable manner, submitting permanently neither to budding, nor grafting, nor laying, nor striking from cuttings. Drought does not suit it; it does not thrive in wet. Heat has no beneficial effect; cold no prejudicial influence. Care does not improve it; neglect does not injure it. Of all the numerous seedlings raised by the Horticultural Society from Mr. Willcock's seeds and distributed, scarcely a plant remains alive. Two are still growing in a peat border in the Cliswick garden, but they are languishing and unhealthy; and we confess that observation of them in a living state for nearly four years has suggested a single method of improving the cultivation of the species.

—C. WOLLEY DOD, *Edge Hall, Malpas.*

ROSES ON OWN ROOTS.

HAVING given this matter a great deal of thought and experimented considerably for the past thirty years, I am convinced that 95 per cent. of the Roses grown to-day, whether for adornment of the flower garden or the forcing for flowers in the winter and spring, are better on their own roots; always provided they are propagated and grown from good healthy plants and given the required season of rest and change of treatment suitable to their several requirements.

If budding or grafting is practised at all, the stock and scion should be of the same family or as nearly of the same qualities in regard to time of growing, &c., as possible; perhaps the worst stock for Tea Roses, if the plants are required for winter forcing, is the Brier; after trying this stock in many ways for that particular purpose for the past thirty years, I have discarded it. This also is applicable to Hybrids for winter forcing, as they never do so well on it as they do on Manetti or Griffaria; the latter is the best of the three by a long way for Tea Roses especially, but for Hybrid Perpetuals for all purposes, if I had to choose between them, I should take the Manetti; but if once Hybrid Perpetuals are fairly tried on their own roots, I think the majority of growers would not want them on any stock. When a Rose is a weak grower, and it is necessary to get it into stronger growth, if it is a Tea Rose, then I would bud it on some good strong growing Tea stock, such as Souvenir d'un Ami, Marshal Robert, &c. To demonstrate this I imported a lot of Roses (Tea and Hybrid) last autumn from several European growers, and in due season potted them up, keeping each consignment separate, and at the same time potting up a lot of my own Roses on their own roots; in every case my own plants have beaten the imported budded plants, no matter what the stock was. Many growers who called here during the past season remarked the difference. I also saw a lot of Rose C. Mermet, imported budded plants, this season planted alongside others on their own roots, and I think I am safe in saying that the budded plants had not produced at the time I saw them more than two-thirds as many buds as those on their own roots, though placed in exactly corresponding positions and receiving the same care and attention.

For bedding purposes, where the plants are required to stand for years, I think the hardy Roses are immensely superior when on their own roots, for while the plant may not be as large when just planted, yet it will soon grow into size and keep on increasing, while budded or grafted plants will in nearly every case be virtually dead in three years, and 90 per cent. of such that are planted in this country every year do not live to see the third year. Why is it thus? Simply because the suckers from the bottom soon monopolise the plant. With inexperienced cultivators the result is disappointment—and when they get the proper attention it is a continual nuisance to have to look them over frequently for suckers and then in the end lose them, which is the case in a great many places I am familiar with. I have a letter lying before me now which will illustrate this better than anything I can think of just at this moment. The writer (a lady) says: "The two Roses Baroness Rothschild and Mabel Morrison you sent me in 1876 have grown to be very fine bushes. They were small plants on their own roots, and I thought when I planted them they would never amount to much, but taking your advice, after having tried a good many budded Roses before and always lost them after two or three years, I planted these two on a new piece of soil and was very agreeably surprised at their growth, and they continued to grow and bloom freely. Last season they presented a most beautiful appearance; the Baroness had over 100 buds and blooms on it at one time and was the admiration of every one who saw it; the M. Morrison was very fine, also many of the others I have since planted, all on their own roots. I do not want any others in future."

This is only one instance of many where Roses are doing much better on their own roots than budded or grafted have ever done.—*American Florist.*

MARECHAL NIEL ROSE.

THE behaviour of this Rose, whether grown in the open or under glass, is as perplexing this season as ever. In some cases it has passed through the long cold winter on walls facing east unharmed, while on southern aspects the wood is much injured. All the growers whom I have had correspondence with on the subject agree that all the injury has been done since the first day of March. Previous to that the plants in most instances were in the most promising condition. This seems to point to the fact that it is the extremes of temperature which cause the mischief. From 10° to 20° of frost at night followed by bright sun during the day, as was the case in the month of March this year, were sufficient to try any hardy subject, much less one so capricious and tender as the Maréchal Niel Rose. But while the cause of the injury to the wood can be pretty clearly traced, I do not see how it is to be prevented in the future. It seems to me to be just one of those penalties that we have to pay for trying to grow in the open air what can only be depended upon under glass. While saying this, I should be sorry to say a word that would deter anyone from planting this Rose against walls on the aspect in which they find it to do best, for if one only gets a few flowers every year, those produced in the open are so superior in point of colour, that I advise all to grow it on open walls who can, although here, in the genial climate of Somersetshire, it does not do well in one garden out of ten, and it is only in some favoured positions in Devonshire that it grows and flowers as freely as when grown under glass.

The behaviour of this Rose under glass is still more inexplicable. Last year I destroyed a plant that was planted in good soil in a warm corner and that only grew to a height of about 4 ft. in six years. At the same time I planted another that sent up a shoot 16 feet long in as many months as the other had lived years, yet I cannot in any way account for such singular behaviour. Both plants were on their own roots and treated precisely the same. I should like to ask if anyone can explain how it is that some plants never extend after they have once flowered. I have had plants behave in that way, and have seen them in the same condition in other places.

Canker is a dreadful enemy to this Rose both above and below the soil, and, no doubt, this is the cause of many failures. I have destroyed plants that have had the knotty burs upon the roots half as large as a hen's egg. These protuberances, it is well known, are the result of canker, and I know of no remedy that will reach this when it attacks the roots; but when canker attacks the stem just above the soil, one is able, by making a mound of earth as high as the affected part, to induce new roots to form, and by these means restore in some measure the vitality of the plant. But when once canker has set in, rooting out the old plant and supplying fresh soil and planting a young one is, in the end, the most satisfactory way of dealing with the disease. J. C. C.

Rose Reine Marie Henriette.—This is sometimes termed a red Gloire de Dijon, but as far as my experience goes, it possesses no quality in common with that floriferous variety, but rather resembles the Maréchal Niel as far as habit of flowering is concerned. At the Bath spring show there were some grand blooms of it staged, and Mr. Cooling informed me they were grown in a large unheated house with Maréchal Niel, the plants being treated exactly the same as that variety. The aim, then, should be to secure as many long and well-ripened growths as possible, and not prune these till after flowering is over. Thus treated it flowers freely, and is really very beautiful both in a bud state and also partially expanded.—I.

Roses planted out for cutting.—A friend who has a lean-to house with a good space of empty wall at the back is desirous of planting Roses against it for the purpose of getting a good supply of blooms. Position and aspect are in his favour, and he is certain to make up a good and suitable border. I have recommended him to plant Maréchal Niel, Mdme. Falcot, Mdme. Lambard, Safrano,

Niphotos, and Reine Marie Henriette, because these produce nice buds, and in that form he finds a ready and remunerative sale for Roses. He can give his house a gentle heat, and his aim is not so much to force as to have a supply between the forced Roses and those that bloom in the open. I think I never before saw Roses breaking with such fine and vigorous promise as this year. The few days ending the 12th of May helped them wonderfully; but, alas, it is again very cold, with a low temperature at night. Winter seems to be appropriating to itself the whole of spring, and treading very closely on the summer.—R. D.

MAGNOLIA CONSPICUA (YULAN).

ON a bye road, which has no outlet (or, rather, only one outlet), in this neighbourhood stands a cottage, formerly inhabited by an elderly Quaker spinster, who had a taste for good things in the gardening way, and who has left her mark on her former abode. At one side of the door is a good old plant of Magnolia Yulan, which fur-

The Chinese Lily Tree (Yu-lan), *Magnolia conspicua*. Engraved for THE GARDEN from a photograph sent by Mr. Greenwood Pim.

nished the subject of the photograph from which our cut is taken, and which every spring bears many scores, if not hundreds, of its snowy, richly perfumed flowers, which when cut resemble huge, waxy Water Lilies. At the other side is a *Magnolia grandiflora*, which is not so much at home. The railings which guard the steps are completely smothered in a dense tangle of *Clematis cirrhosa* (also figured in the cut), old-fashioned Roses, and the pretty variegated *Smilax aspera*, while a *Wistaria*, with stems as thick as one's arm, hangs its lilac clusters in myriads over the porch. Behind the house are some choice shrubs, amongst them a fine specimen of *Hypericum nepalense*, and others unknown to me. Few climbers are more graceful than *Clematis cirrhosa*, its delicately-cut dark evergreen foliage contrasting well with its curious and pretty, though not very showy, pale yellow blossoms. Its leaves are its strong point; anything more graceful than its shoots

and leafy tendrils can scarcely be imagined, and that they are as available in mid-winter in the open air as in summer, is a further item in its favour. I have even seen its bell-shaped flowers peeping from a canopy of half-melted snow. GREENWOOD PIM.

Monkstown, Dublin.

FRUIT GARDEN.

W. COLEMAN.

PACKING HOTHOUSE FRUIT.

MUSCATS.—Last week I briefly described my own method of packing Hamburgs, and, as a matter of course, similar varieties of Grapes, but time and space prevented me from exhausting the subject by touching upon Muscats. These and all the Frontignan race being more tender than Hamburgs require greater care, and the less they are handled the better they will keep, as any undue pressure causes them to change from their delicate amber to a dirty brown almost immediately after they are opened and exposed to the air. To avoid this, materials of the softest kind only must be used, and of these they must have sufficient to prevent them from moving on the journey. The width of the boxes in which the bunches are to be packed transversely must be regulated by the length of the latter, but, unless they are extra large and heavily shouldered, the depth need not exceed that recommended for Hamburgs; whilst for small taper bunches 6 in. to 7 in. will be found ample. Having thoroughly dried the materials, boxes included, prepare the latter by laying a good 2 inches of Moss evenly over the bottom, line the sides and ends with strips of wadding folded in silver paper, and proceed, as before, by poising the right-hand end of the box to a sharp angle. Place a double sheet of silver paper across the lower end of the box, allowing at least two-thirds to run along the bottom, previously papered to keep down the Moss. Cut the first bunch; lay it lengthwise across the end of the box with its shoulders in one corner; turn up the ends of the paper, and draw them gently, but firmly, over the bunch towards the lower end. Then take a strip of wadding, in length equal to the width of the box and 4 inches or 5 inches in depth; place it against the bunch to form a division; lay in another double sheet of paper, and proceed by laying the next bunch with the stalk in the opposite direction; turn up the ends of the paper as before, and draw the second bunch well up to the first. Introduce another strip of wadding, and repeat until apparently the box is full. This, however, will not be the case, for by raising it to a sharper angle very slight pressure against the last bunch will make room for one, perhaps two, more, which must then be added. Force a little Moss into all available spaces between the wood and the lining; fold the upstanding ends of the paper over each individual bunch, commencing with the first; enclose the weight, secure the lid with two very small nails, and cord singly, or two boxes together, tightly. Although wadding is apt to sweat and become hard when placed in contact with moist fruit or damp boxes, this does not happen when particular attention is devoted to drying, and double sheets of paper throughout prevent it from touching the berries. These directions apply specially to the packing of dead ripe or well-kept Muscats for long journeys in the autumn. Early summer Muscats, which growers cut as soon as they are passable for market, do not require, or if they do, they do not always get the wadding divisions between the bunches. Whatever is worth doing at all,

however, is worth doing well, and for this reason a matter so trifling should never be neglected.

THICK-SKINNED GRAPES, like Lady Downe's, Mrs. Pince, Black Prince, and Alicante, whose bunches are long and taper, pack best in the transverse way, but it is not necessary to place anything between them. Like Hamburgs, however, they should be placed very close together; indeed, the tighter they are packed the better they travel, as there is no possibility of friction. A box 6 inches in depth will be found quite deep enough for a very fine sample of Lady Downe's, but of two sizes it is better to have them rather deep than shallow, as the top berries must be clear of the paper, which should be drawn tightly over the box and nailed down with the lid. Where soft Moss is scarce, as I know it is in many parts of the kingdom, fine paper shavings form the best substitute. Whichever is used, it should be forced down between the sides of the box and the lining until it begins to form an arch next the lid, when the boxes may be turned wrong way upwards without injuring the Grapes.

EFFECTS OF THE WINTER ON FIG TREES.

MR. COLEMAN rightly accepts the past winter as a test one for the Fig in the open air. Possibly he is right in his conjecture that it has hardly passed through such a trying spring since Cardinal Pole laboured so zealously for its extended cultivation. As Mr. Coleman challenges non-protectors to record the condition of their trees, and almost promises to give up protection and all such fussy and untidy contrivances if the embryo fruit as well as the young wood are safe, and the trees give promise of one good crop of Figs, I respond to the challenge, and forward you a box of wood to enable you to judge for yourself. These are by no means from trees in a sunny corner, but from those on several aspects in a cold draughty yard, behind a lofty range of glass, in which sunshine is conspicuous by its absence. Whether the trees are "poverty stricken," or not, is another matter of which the accompanying cuttings will enable you to judge, and about which I shall have more to say, as I hold that a starving treatment is an essential element to the safety of the Fig without protection in the open air. By the way, as Mr. Coleman seems to have uncovered his Figs soon after April 20, and as he is specially anxious to know the condition of unprotected Figs, he will doubtless be so good as to inform us how it has fared with his Fig wood and embryo fruit exposed to the bitter weather occurring between April 20 and May 20. An answer to this inquiry may afford your many readers some satisfaction in regard to the weakest feature of protection, viz., its removal. It may sound like a bull, though it best expresses the most vital practical truth, to say that the dangers of protection do not consist in putting it on, but in taking it off. No fruits can look more promising than Figs when they are uncovered. No fear of any scarcity of living points well furnished with embryo fruits. But no one knows better than Mr. Coleman how often these embryo fruits are blighted, shrivelled up, or drop off after uncovering. When this happens, as no doubt it has in most cases this year, especially where Figs have been uncovered so early as the 20th of April, then the covered Figs start in the race for fruit a month or two behind the uncovered ones. Granting the latter will bear but one crop of fruit in the autumn, the covered trees that drop their embryo fruit after uncovering will ripen no fruit at all, as their shows will be too late to reach maturity before winter, and thus Fig protectors come to grief between two stools or crops. The fruit is so forward, that chills such as we have had this May bring them all to grief or the ground, the second being too late to ripen before the first frosts of autumn are upon them. Neither is it at all clear how Mr. Coleman's "plentiful feeding" will prevent this failure between

two crops, or foster the maturing of the wood. If you would have Figs from the open air, feed not at all would be my advice, as it is my practice, if practice may be defined as a negative, of doing nothing. While venturing thus freely to criticise some of Mr. Coleman's views, I heartily endorse his high estimate of the lusciousness and even commercial value of the English open-air Fig. It not only may be, but is grown year by year of a quality and flavour equal to the best hothouse fruit; while as to comparing Smyrna Figs with English, as well compare French or Italian Grapes with our finest hothouse fruit.

That Mr. D. Walker, of Tunbridge Wells, should have written to say that his open-air Figs are perfectly hardy, even under the pruning and training operations he describes, is not surprising. But their perfect hardiness in East Anglia, over forty miles from the coast and in a cold locality, is another matter, and is largely, if not wholly, due to the starving treatment to which they are subjected. As before stated in THE GARDEN, these trees are planted in a stoneyard, almost as hard as iron. This was fifteen or more years ago. No soil was given at planting; they have had none since, nor any liquid manure or water, only what falls upon them. So essential do I consider starvation to hardiness and fertility, that I do not believe these Figs would ripen if planted on Grass, like Mr. Walker's, or even if treated according to Mr. Coleman's instructions. The struggle for life must needs be severe, and is an important factor in establishing the hardiness and heightening the fertility of the Figs. No roots appear on the surface, and if they did they will quickly wither up and perish, or be crushed by cart or carriage-wheels. As to their numbers or conditions underground, we know little and care less, so long as the top growths are short, stout, fertile, and yield an abundant supply of fruits that develop into such masses of lusciousness as the season advances, that many of them rain down nectar from their opening ends, or almost open themselves inside out in the overflowing fullness of their saccharine qualities. D. T. F.

* * * Samples of Fig wood with embryo buds were sent with the above. The wood had been cut from plants growing without the slightest protection on four different aspects, viz., south-east, south, north, and north-west. All the specimens sent were uninjured by the late severe winter. The wood from plants on the northern aspect, on which the old Brunswick is said to ripen tremendous crops of fruit, was the strongest. The wood from plants with a southern exposure was very short-jointed, and showed a great quantity of embryo buds.—ED.

Hardy fruit prospects.—The terrific winds which prevailed throughout the kingdom about a fortnight ago led many people to think orchard fruits had been much injured. A careful inspection of a number of large Apple and Pear trees in this neighbourhood is, however, satisfactory, and, judging from the clean, healthy appearance of the foliage, combined with the lateness of the season, I have good reasons for thinking this important crop will be a good one. Cox's Orange Pippin and the majority of the choice varieties of Apples are unusually full of fine robust flowers, and being free from grub, the prospect is highly satisfactory. Many people like to see the leaves well in advance of the flowers, but, provided we escape late frosts, I prefer the reverse order, as late flowers often indicate imperfect maturation of the buds. Planters on the outlook for bright, handsome flowers should note Scarlet Nonpareil, Lady Heniker, and Izard's Kernel, now generally catalogued as Tom Pitt. The last produces handsome crimson fruit, alike good for vintage, the kitchen, or the market.—W. C.

Sparrows and fruit trees.—Within a few yards of my room window stands a Ribston Pippin Apple tree full of bloom. I have found a pleasant morning's amusement in watching the sparrows as they fly to and fro from house-roof and tall trees behind, alighting in the Apple tree and proceeding to peck about them vigorously in all directions, now at the flowers, now at the leafage, then cleaning their bills on the stems and hopping off to another

branch to perform further—what? Aye, that is the point, because at first sight it looks as if they were wantonly picking the flowers to pieces or else eating the pollen cases on the anthers, but for the fact that the foliage gets its turn also, and they do not seem to harm that. I gathered a bunch of the Apple bloom and could not detect mischief in any shape, or even aphid, but only two or three tiny black flies. I therefore infer that the sparrows were finding food in these little insects, which may have been harmful or harmless.—A. D.

RED SPIDER.

I AGREE with Mr. Coleman that the best way of repelling the attacks of this formidable foe is to adopt as generous a system of culture as possible. A point of the highest importance, however, is to maintain a very healthy, active condition of the roots. No plant is more open to the attacks of red spider than the one which is suffering either from a deficiency of roots or which has had them injured in some way. It is of but little use endeavouring to feed, for the purpose of resisting insect attacks, a plant whose roots cannot readily take up the nourishment given them. Market growers seldom suffer much from this pest, because their method of culture consists in promoting root-activity to the highest possible point, in conjunction with supplying their plants constantly with as much moisture and food as they are capable of taking. From the time the cuttings are struck until they become specimen plants they never want for anything needful to a healthy existence. It has often appeared to me that red spider is, as it were, continually hovering round those plants it loves to prey upon, waiting for the moment when a slightly feeble condition may enable it to obtain a footing. Why is it that no traces of this insect are seen all the time the plants are growing away luxuriantly? It fastens on them the instant they suffer in a dry time for want of moisture either at the roots or in the atmosphere; hence the necessity for a never-relaxing vigilance in keeping up a due supply of root moisture. Once red spider obtains a lodgment it is a matter of great difficulty to eradicate it, but taken in hand energetically on its first appearance its multiplication can be effectually checked. We grow here a quantity of Strawberries under glass, and, as everyone knows, they are extremely susceptible to the attacks of this insect. I always keep a solution of soap in readiness, and act on the stitch-in-time principle by immediately well washing the foliage with soapy water. This I repeat at intervals of two or three days for a week or two, which generally effects a cure. The great point is to have the solution always in readiness, so that not one day is lost in applying the remedy. I now make a rule of having the soapsuds from the house stored away in tubs, which saves trouble. If the syringing is timely done it is not necessary to use the solution strong. I put half a pint in a gallon of water. This does not discolour the foliage; on the contrary, I think that the leaves are improved in appearance, and it is sufficiently strong when frequently applied to render the under surface of the leaves unpalatable to the spider. It cannot be too well understood that a light syringing is of no use whatever. The water must be applied to the foliage with force, at the same time taking care not to injure it. The frequent overhead sprinklings that are generally practised often do more harm than good. Instead of continually wetting the upper surfaces of the leaves, the labour thus bestowed would be better employed in thoroughly washing the undersides of the foliage. Two good washings weekly will do more to keep plants free from spider than three or four daily sprinklings. One thing much favours the spread of spider, and that is allowing the temperature to rise suddenly before giving air, by which this pest is often largely increased. I have alluded to the importance of maintaining root-action at par, as one means of warding off this pest. This season I have had one more example of how a torpid condition of the roots invites its presence. It happened that one end of a long bed planted out with Strawberries under glass was much trodden on during the winter. When turned over in February

it looked rather close and sour. The consequence is a marked difference in the vigour of the plants; in that particular spot they have never grown freely. The other day I noticed spider on them, and examining the soil round the roots of the plants, I found that the roots had never started well in it. Where the soil was sweetened and the plants grew vigorously there is no spider. This is, of course, only what might be expected; anything that lowers vitality invites disease. It is as well, however, to direct attention to a fruitful, and I think, with many, an unsuspected source of evil.

J. CORNHILL.

ORNAMENTAL APPLE TREES.

SOMEONE was inquiring lately in THE GARDEN about Apples for ornament. The greatest difficulty would be to find any that were not ornamental. Left to themselves or to Nature, most Apples form noble round-headed trees, with form and foliage of the highest value in any landscape. The leaves of most sorts also fade into gold in the autumn that rival the beauty of their mellow fruits. And the latter are so richly painted with all the colours of the rainbow, and so infinitely varied in form, as to rival any tree or shrub grown for the ornamental results of its berries or fruits alone.

While as to Apple blossom, what colour or word-painter has ever revealed or expressed half its charms! Pink has done its utmost to exhaust its beauty among the Apple bloom; and the artist who would learn the inexhaustible prodigality of its wealth must go long to school and become an earnest student among them.

Next to the infinite variety of colour among Apple blossoms, covering the entire distance from the deep rose of the Manks Codlin to the blanched white of the Calville Blanche—a variety in which the bloom predicates the colour of the fruit—a rare thing among Apples—the amazing prodigality of bloom is the main feature in the superlative beauty of Apple trees.

Doubtless it was this feature that your correspondent had in view in his inquiries about Apples for ornament. For profusion of bloom there are perhaps no Apples that excel the common and some other Crabs, many of the cider Apples, chance seedlings, and most of the Codlins, such as the old Keswick, Lord Suffield, and the Irish, or Manks Codlin, already named. For bold, fine-coloured, rather large blossoms, the New Hawthornden, Non-such, Golden Noble, Norfolk Beautin, Cox's Orange Pippin, Golden Drop, Small's Admirable, Warner's King, and D. T. Fish are among the most conspicuous. King of the Pippins is also fine, but rather light, as are the following, some of which, and most notably the Worcester Pearmain, the highest coloured of all Apples, is pure white. The Juneatings are almost white, and large and cupped, and the following are large and light: Margil, Gravenstein, Norfolk Beautin, Red Astrachan, Cox's Pomona, and Alexander. These highly ornamental flowering Apples are very far indeed from exhausting the list. I trust others may be induced to add to them, and in doing so many will be surprised to find that few flowers vary more widely in size and colour than Apple blossoms; while even the variations in form are very much greater than any casual observer would suppose. Hence, while all are ornamental, some are infinitely more so than others, and more deserving of being planted in woods and parks, as telling and most attractive features in home landscapes.—D. T. F.

— Amongst rich-coloured Apple blossoms, I find none of so deep a hue as those of Nelson Codlin, a variety not too well known, but a most meritorious one. The tree in habit resembles Lord Suffield, but is more enduring; hence it does not grow large. It bears crops regularly, for my tree is never without fruit at the proper season. It opens its blooms later than Lord Suffield does, and is really a successional kind, the fruits being of the same shape as are those of that familiar kind, but are greener. It might have been a parent of Lord Suffield, so much does that kind favour the Nelson Codlin. Ere the bloom opens, the buds show petals of a deep blood-

red, and as the weight of fruit yearly pulls down the branches, causing them to become pendulous, the bloom-buds stand out with great effect. The flowers when expanded are large and high-coloured. Another very showy Apple when in bloom is Grange's Winter Pearmain, a little-known kind. I have several trees of this, strong growers, as much so as is Blenheim Pippin, but more erect. The fruits are large, conical, ribbed, and in the sun colour fairly well; good for kitchen or dessert, and keep well till March. Ordinarily a fair cropper, this season the trees are blooming with wonderful profusion, although the same thing can be said of many kinds, for I can look out upon hundreds of orchard trees all as full of bloom as well can be, although many lack colour. Whilst the recent hurricane has left Pears and Plums almost devoid of bloom, the Apple trees seem uninjured. Generally, little harm seems to have been done.—A. D.

SHELTER FOR FRUIT TREES.

SELDOM have we had a more striking illustration of the value of shelter or wind-breaks for fruit trees than during the past week, when violent gales of wind, accompanied by heavy showers of rain, more like mid-winter than the third week in May, made us tremble for its effects on our fruit trees just in full bloom. We had been congratulating ourselves that, after all the long and trying winter, we should at least be safe from spring frost, and that an extraordinary crop of hardy fruits must follow, when our hopes were rudely shaken by such a gale. In looking round after the gale has subsided its marks are plainly seen where it had full sweep, the tender foliage being quite blackened, and in many places torn from the trees, so that orchards fully exposed to its effects have suffered severely, and the crop must be very much reduced; but, thanks to an unusually abundant bloom, there may be enough left yet for a crop. Being situated close to the sea, we get quite a full share of wind at all times, and have therefore taken the precaution to provide shelter all round as far as possible, and find that a screen of trees appears far more effectual than a wall, for the wind gets more broken, as I observe in one of our fruit plantations the tops of the trees are cut down to the level of the wall as if a fiery blast had swept over them; while for a long distance inside the tree screen they are perfectly safe. It is a singular fact, that in different parts of the country one has to provide shelter in quite the opposite direction to what they do in others. When living on the east coast I well remember how the east wind used to cut up our gardens in spring; while here on the south coast, although nothing thrives during an easterly wind, the trees are not so much cut up as they are by the westerly gales, so that in laying down any rules as to shelter belts one must allow great latitude for the locality and prevailing winds. If situated close to the sea, I think the atmosphere gets charged with saline particles that add greatly to the destructive force of the gales, especially in their effects on tender foliage. People talk of the mild south coast as if it were a paradise for gardeners; whereas it is difficult to get a fresh green leaf even of the hardiest shrub in winter, as they get so cut up by the frequent buffetings of wind we get from the west. I think we must pay more attention to the matter of shelter for fruit trees than hitherto if we are to be successful in growing regular and constant crops; for, although we are apt to lay all the blame of loss of crop to spring frost, I question if they are really so disastrous as many imagine, as there can be little doubt but that the blossom fails to set and drop off from many other causes than being actually frozen, and there can be little doubt but that when cold, chilly winds prevail the sap of the trees gets so much checked that the bloom is literally starved on the tree and drops off from sheer exhaustion. We cannot hope to improve our climate, but we can do much to modify the harshness of the winds by providing tree screens on the exposed sides of our orchards, as the most casual observer will note that in the centres of the fruit plantations the trees shelter one another to a considerable extent.

Gosport.

J. GROOM.

AMERICAN NOTES.

THE largest American sweet Chestnut which we are acquainted with is the Great American, and it is a splendid nut indeed. It will pay our propagators to find these best sorts of our native Chestnut and propagate for all they are worth. The demand for trees is constantly increasing, and good varieties of the sweet Chestnut will be sought after.

The Yellow Transparent Apple.—All you say of the Yellow Transparent Apple is true, for great areas of our country, and even of the great West, but other members of this family we regard as still more valuable for the West, as the trees are hardier and less subject to twig blight. The Thaler, Grand Sultan, and Blushed Calville on our grounds give far better satisfaction, and their fruit is quite as early, handsome, and good.

The Dewberry and the Juneberry.—The Lucretia Dewberry is exceeding our expectations at the west, but on our northern borders it is soon to be eclipsed by select native sorts, which will soon be in the market. I am able to speak well of the Dwarf Juneberry. We have varieties from the Hartz Mountains, in West Europe, and from several points in East Europe. We also have fruited a dozen or more varieties found in the Eastern, Central, and Western States, and the Amelanchier alpina of Western Texas. From all sources the plants are perfect in foliage and hardy in winter, and all of them are immense bearers of good fruit. In some respects the variety from Central Russia and from West Texas we place ahead.

Juneberries.—The lusciousness of the Strawberry captivates on introduction; its peculiar combination of pleasant tartness and sugary sweetness, just at its season, conquers every heart and taste by storm. Two weeks of indulgence, however, bring out its acidity, and make it felt in a way less pleasant and agreeable, so that even the milder tartness of the Raspberry is often too much. Right here comes the Juneberry, with its unobtrusively mild and indescribably pleasant flavour. It does not take us by surprise. It is not a dazzling beauty, like the Strawberry, captivating our hearts by storm, but by its innate goodness it wins its way irresistibly into our good graces; and it stays there, too.

Selection of site for Peaches.—Years ago we were induced to plant quite a large Peach orchard in a sheltered location, high up on the hills of Western New York. The land, being in close proximity to the barnyard, was in a high state of cultivation, the result of previous repeated and, for farm land, almost extravagantly heavy dressings of stable manure. The varieties selected included the Crawfords, Early York, and other standard, but rather tender sorts. All made a rampant growth while they lived, but every spring following found a large percentage of the trees lifeless, until, about four years after our planting venture, the last one had departed this sub-lunary vale of tears. The forced, sappy wood was unable to endure the rigours of Western New York winters. Had we, instead, selected a piece of rather thin soil and manured it highly with potash and phosphates, especially with kaimit and wood ashes, and planted hardier trees, like Wager, Globe, Beatrice, or any of the first early sorts, the orchard, in all probability, would be flourishing and bearing fruit to this day, and have brought us some money, instead of a complete failure. Experience is a most excellent teacher, but a rather dear one, unless you learn from the experience which your neighbour is paying for. This is perfectly legitimate, and we tell our story that the young planter may be able to learn his lessons at the least possible expense to him.

How to make grafting-wax.—Melt and boil together one pound of rendered beef tallow, two pounds of wax and and three pounds of rosin. Some people prefer a pint of linseed oil in place of the tallow. For use in warm weather, a little more rosin may be added. When the mixture has been boiling for some time, pour into cold water and work as if "pulling" molasses candy.

Cheap fruit jellies and jams.—Dr. Cyrus Edson, one of the chief inspectors of the New York Health Department, tells, in "Babyhood," about the composition of cheap fruit jellies, as they are found

put in fancy packages in our grocery stores. A sample of a "currant" jelly consisted of the following ingredients: Dried Apples, water, low-grade glucose, tartaric acid, and arsenical fuchsine (a red aniline colour). To this mixture was added a sufficient quantity of French glue to give it the consistency of jelly. A large package of salicylic acid was also found stored away in a cupboard, which, after some pressure had been brought to bear on him, the proprietor admitted he used in warm weather "to keep his jellies from spoiling." These goods were seized and destroyed on account of the poisonous arsenical fuchsine used in colouring them. A thorough inspection of the jelly factories in New York City revealed the fact that all were manufacturing goods after similar formulas. The use of fuchsine and salicylic acid was prohibited, and the manufacturers compelled to substitute gelatine for glue. Commercial "currant" jelly is now composed of dried Apples, water, glucose, tartaric acid, carmine or aniline sugar-red, and gelatine. Mix, boil, and strain. Other fruit jellies are made by diminishing the tartaric acid and substituting other colouring matter. The dried Apples used in the manufacture of these jellies consists very largely, if not altogether, of dried skins and cores—the refuse of the large evaporating establishments (as we have learned by a thorough inspection of several of the latter). These jellies are far from being wholesome, and the whole business is a fraud on the public at best. We appeal to every true housewife and mother to avoid the cheap stuff and to rely henceforth on home-made fruit jellies. Buy good fruits and you can easily make all the wholesome jellies that your family will need. The formula is simple and the preparation easy. Here is Dr. Edson's recipe: "Take juice of fruit, freshly pressed, white sugar a sufficiency. Boil some time, strain and cool rapidly." The manufacture of adulterated jellies is a fraud, an injury to the health of the people (by substituting a nasty compound for wholesome fruit juices), and a threat to the fruit interest (by diminishing the demand for good fruits)—in short, it is the horticultural oleomargarine.

SEASONABLE WORK AMONG FRUITS.

ORCHARD HOUSES.

WHERE the forcing orchard house sends the first dish of ripe Peaches to the table, the early varieties, including the best English seedlings A Bee, Early Grosse Mignonne, and several of the American sorts, will now be ripe or approaching that stage. When this change sets in it is a good plan to place all the most forward trees in a dry, airy part of the house, in which syringing and watering can be reduced to a certain extent, as an excess of water is not conducive to good flavour. This change must not, however, be carried to an extreme, as Peaches in every stage must never feel the want of this life-sustaining element. When the most forward Peaches are fit for gathering they should be detached when dry and cool, and placed in shallow boxes in which they will keep for some days in a dry, airy fruit or Grape room. If wanted for market, full size and colour are the leading points, and as these are attained long before the Peaches soften to the touch they should be detached, sized, and packed, and sent off without delay. A few days often make a considerable difference in the price; add to this the fact that all large fruiterers prefer storing and ripening up the fruit themselves, as they can then pick them out without spot or bruise, and, whatever the consumer may think, the grower has two strong reasons for starting early. When the early trees have been cleared they will require good syringing to cleanse the foliage, and more water must be given to keep the roots in condition until the time arrives for potting.

Succession houses containing the leading mid-season sorts must now be freely ventilated, not only through the early part of the day, but again on mild evenings; a little time apparently may be lost, but if Peaches worth eating are the first consideration, a free circulation is quite as important as fire-heat and water. Good top-dressing, little and often, must not be withheld, and weak liquid of some kind will be found a very important factor. We now

syringe all our trees twice a day with pure soft water, to which once or twice a week a dash of clear soot water is added. The first being free from lime does not disfigure the fruit, and the second is an excellent insecticide and stimulating agent. The time for syringing now ranges from six to eight on fine mornings, and from three to four in the afternoon when the ventilators are closed, with sun-heat to favour swelling. The temperature is allowed to range from 56° to 60° through the night, with a chink of air, which is shut off at six o'clock, to favour the morning *douche*, and the house is kept close until sun-heat renders fresh air necessary. A gradual rise is then allowed, to carry the day temperature to 70° or 75°, when a few degrees more do no harm, provided the heat does not fluctuate to any extent and the house is freely ventilated. Next, as to insects, we find it the cheapest and best plan to smoke lightly for green-fly before these insects put in an appearance, and for spider we do not accept an excuse, as something must be radically wrong with the roots of the trees or the man who uses the syringe when this little pest gains a foothold. When the fruit in this house has passed the stoning process, the final thinning must be made with a bold hand, as the great failing, especially amongst amateurs, is over-cropping—that is, where they have a chance, although many of them know well that too much fruit means mediocrity and want of flavour. One full-flavoured Peach is worth a dozen bad ones, and when it is borne in mind that pot trees have barely a foot of compost to grow in, it is sheer waste of time and wrong to overload them.

Late houses.—Where these have had the assistance of a little fire-heat, the fruit will now be safe and fit for steady thinning. A few may be left to allow for dropping, but well-managed trees do not often cast their fruit in June and will repay timely attention to this important matter. Trees in late houses should be well disbudded and carefully pinched, to concentrate the sap and prevent them from becoming gross before they feel the weight of the crop, but the work should always be performed piecemeal. Many of the shoots run away quickly, especially near the tops of pyramids, and unless these are taken in hand in time they rob the lower parts, and the trees soon degenerate into half standards. If the fruit is wanted as late as possible, steps should now be taken for retarding its progress through the early stages of its growth by giving an abundance of air on all favourable occasions. Of this, however, there is little danger, as trees in cold houses to which fire cannot be applied are quite three weeks later than they were last year.

MELONS.

Where winter Cucumbers give way to Melons the plants should be a foot or more in height and thoroughly established in the fruiting pots in the nursing pit before the Cucumbers are destroyed. By adopting this plan the most will be made of the Cucumbers, and, provided the preparations are satisfactory, a very short time will suffice for running the Melons into fruit. One thing, however, is very important, and that is cleanliness; a thorough spring cleaning of all glass and paint with soap and water, and cleansing of the walls with a wash of quicklime and sulphur. The plunging or bottom-heat bed having been in work since last autumn, its entire removal will most likely be necessary, if not on the score of decay, certainly to favour the destruction of worms, woodlice, and a host of other marauders, which soon multiply in hothouse pits. When the pit is quite empty, it should be well drenched with boiling water and washed with hot lime, when a fresh start may be made with every chance of success. In order to dispense as much as possible with fire-heat the new beds should be well made of sound fermenting leaves and firmly rammed before the pots are plunged to prevent the heat from escaping. When the heat is up and satisfactory, the pots may be plunged nearly to their rims, a good sod of heavy turf being placed under each to sustain the crock roots and prevent them from running away into the decaying manure. When I adopt the pot system, I always plunge the pots 2 feet from centre to centre, and allow about 5 feet

run of trellis for the vines; if space admits, a second row is plunged in the same bed, and scarlet-fleshed varieties in 12-inch pots are grown over the top-heat pipes. Scarlet-fleshed Melons, never so good as the green, always attain their best flavour when finished off in the hottest and driest part of the house, and the better to avoid the drying of the roots, we place each pot in a shallow box containing an inch or so of rich compost. This material filters the liquid on its way from the crocks and forms a useful feeding ground for the roots when the fruit is swelling and requires rich stimulants. Pans or saucers might be used, but from these the water could not pass away, and, much as the Melon enjoys liquid, it does not thrive upon it in a putrid or stagnant condition.

Frame Melons, solely dependent upon heat from fermentation, have not had a good time; consequently they are much later than usual. Constant attention to the linings, which should be renovated back and front alternately, is still imperative, and good covering at night is equally important. As growth advances and the roots push through the hills, more compost which has been lying in the frame for some days to get warm must be added and firmly packed, or rammed, to give solidity. Many people go to unnecessary expense by giving frame Melons cartloads of soil where barrowloads would answer equally well, and then complain that the "light is not worth the candle." Quality is of more consequence than quantity, hence the importance of getting fresh stiff loam that will grow them well without the aid of manure, of compressing it into a firm mass, and feeding when the hungry roots have literally devoured it. Earlier plants now swelling off crops of fruit will require liberal feeding with diluted liquid, and good syringing under as well as over the main foliage, also round the sides of the frames, but on no account must the collars of the plants be saturated. Indeed, it is questionable if a semi-moist condition of the soil about the stems is not one of the most common causes of canker; therefore the better to escape sudden collapse each plant should occupy a cone that will carry it high and dry, even when the main body of the bed is flooded. When the Melons have been thinned it will be necessary to elevate them on inverted pots to keep them partially peeping through the foliage and safe from woodlice. Gradually the main leaves, which must be kept free from lateral growths, will subside, and the fruit will have full exposure to sunshine, which cannot be too strong for Melons in this country.

CUCUMBERS

in heated houses will now take thorough soakings of warm liquid once or twice a week, and copious syringing at closing time in the afternoon. We do not care to wet the fruit on bright mornings, but all available parts of the plants, the walls, and the beds are well moistened, and water is dashed over the floor to keep up a supply of vapour. Red spider is the worst of all enemies to the Cucumber grower, but it makes slow progress where water is freely and judiciously used, and good feeding and light cropping are strictly adhered to. Another important point is constant manipulation of the young growths, which should be pinched at the first joint beyond the fruit and neatly tied down to prevent the foliage from touching the glass, and ensure a continuous circulation of air. If this does not prevent flagging under very bright sun, some very light shade for a few hours in the middle of the day may be advantageous, but on no account must this be followed up until the foliage is too tender to stand without it. If old or heavily cropped plants show signs of exhaustion, the liquid waterings may be supplemented by extra rich top-dressings composed of light turfy loam, leaf mould, and old lime rubble, little and often whenever the roots show upon the surface, otherwise the first and last, minus the leaf-mould, will support a lasting growth and produce fruit of the finest flavour. Many people think one Cucumber is as good as another, but this is a mistake, as too much manure or too slow a growth produce fruit that is flat and bitter. Some sorts, again, are not so easily affected as others. Telegraph, for instance, is considered

one of our best all-round Cucumbers, and none, perhaps, can touch it for eight months out of the twelve, otherwise the handsome black-spined varieties, so well adapted for summer-frame culture, would not have dropped so completely out of our lists.

Frame Cucumbers.—Beds made up and soiled early in the past month will now have the best of the year before them. If the plants were put out very small and pinched, as I have often suggested after they got established in the soil, the young vines will now be pushing their way to the extremities, and any that are taking the lead may be stopped, not so much for fruit-bearing laterals as to throw strength into their weaker neighbours. The hills, too, must be regularly soiled, as the roots show through the sides and made more or less firm according to the nature of the compost. Like Melons, they sometimes receive more soil than they actually require, especially when the old-fashioned method of pegging down at every joint is practised and the crop is regulated by the wants of the family. The weather being so cold, with a sharp wind still blowing from the north, ventilation just now is a ticklish matter. Still, the plants must have air or constant shade; therefore, the best and safest plan is to tilt the lights in front instead of at the back until winter gives way to summer weather. Linings and coverings are still as necessary as ever, and must have regular attention. To maintain the bottom-heat of the bed, a good body of well-worked manure should always be on hand, and from this the linings back and front should be renovated alternately. In course of time it may be well to pull the linings down to the ground and rebuild them entirely anew with fresh materials; the work does not take up much time, and the improvement, provided steam is kept out of the frame, is truly magical. Early closing on the brightest afternoons is another great factor in the maintenance of health and the production of good fruit, which must not be overlooked. If hot, soft water at 80° or 85° can be secured, the plants and sides of the frames should be well syringed as the lights are shut down, certainly in time for the moisture-laden atmosphere to rise to a temperature of 90°. W. C.

Summer pinching of Currants.—I am quite unable to see how anything but a reduced crop is gained by the summer pinching of Currant shoots as directed by "J. G." in THE GARDEN, May 21 (p. 470). In the first place, there is the expense of going over and carefully pinching extensive plantations, and in the second place there is the certainty that every shoot topped "in the full flush of growth" is robbed of so many clusters of fruit that would otherwise have been produced towards its extremity, while the gain by driving the sap into the base buds is worse than nil. Black and Red Currant shoots produced annually from the older wood almost invariably bear at any joint their whole length, and the finest clusters are always nearest the top. "J. G." by pinching these best clusters off may drive a portion of the strength into the bottom clusters, but he hardly adds to their number, while he loses the top clusters altogether. There is no getting away from this conclusion, as anyone will see who chooses to examine his bushes at this season. Gross shoots or suckers proceeding from the root do not always bear all the way up, but such should not be permitted to grow at all except to fill up gaps. The main crop is borne on the lateral branches and shoots of the main limbs, and these nearly always bear their whole length. As regards the plea of excluding the light from the foliage, that is easily prevented by judicious thinning out in winter. Under such conditions the foliage of the Currant has always plenty of light and is well developed and ripened. If the Currant tribe did not ripen their shoots to their extremities it would be different, but they never fail to do so, and on healthy fertile bushes no "useless wood" is produced.—J. S. W.

Applying liquid manure.—It is chiefly in the summer-time when plants are in active growth that liquid manure is applied to them. It is a mistake to give plants that are not well rooted much of it, but when they have plenty of roots, and are growing

freely everywhere, it is very beneficial; but as liquid manure is often a scarce and always a valuable commodity, it should be used in such a way as to secure the best possible returns from it. In the case of plants in pots when they have many roots they are always apt to become quickly dry in hot weather, and many of them are often so dry that when the water is given them a large quantity of it passes through the soil and runs to waste. It is a mistake to allow manure water to be wasted in this way, as it does the plants little or no good. The most economical and advantageous way of applying it to all plants in pots is to make the soil and roots wet with clean water first, and then water with liquid, as the moist soil retains all the best properties of the manure, and this is the point to secure. This rule also holds good in the case of fruit trees of all kinds, and vegetables as well.—CAMBRIAN.

FLOWER GARDEN.

SABBATIA CAMPESTRIS,

OF which the annexed cut gives an excellent idea, both of its graceful habit of growth and floriferous character, is one of the most charming annuals we have, even taking into

Sabbatia campestris.

consideration the great numbers of showy plants we get from its native country, North America. It belongs to the Gentian family, and although the genus Sabbatia numbers a good many species, very few as yet have found their way into cultivation, and in all probability not more than two or three are to be found in gardens at the present time, *S. campestris* and *S. chloroides* being the most common; the latter is a biennial and a most charming flower. It grows from 1 foot to 2 feet high, and from a loosely plicated stem is produced a profusion of large deep rose-coloured flowers. It is found on the margins of brackish ponds, &c., from Massachusetts to Virginia, and flowers from July to September. It stands in the open, but we prefer growing the plants in pots in a cool shaded frame the first year, or through the first winter, and placing them in the open air about the end of March or early in April. A moist situation should be selected, well sheltered and shaded from the mid-day sun. *S. campestris* differs widely from the above in its requirements; the drier and sunnier the position the more satisfactory will be the result. Although

it does well sown in the open air along with other annuals, it is always late in flowering, and this plan is adopted to get a succession of flowers; the first flowers coming from those plants sown in pots about the beginning of February, and pricked out when all danger of frosts is gone. When sown in the open air, a nice sunny position should be chosen where the soil is rich and well drained; the seeds should be sown as thinly as possible. The flowers are lilac-coloured, over an inch in diameter, and produced in such abundance as to give a striking effect in large clumps or patches. Found on the prairies of Arkansas and Texas. K.

HARDY PLANTS FOR CUTTING.

This is a good time to make notes of reliable hardy plants for supplying the cut-flower basket, as it is only by making a careful selection of varieties to follow one another that anything like a continuous supply can be ensured. Where one has a good collection of flowering shrubs, beds of Roses, and a mixed herbaceous border, there is always something to cut; but, in addition to this, it is a great advantage to have a few good-sized beds of plants that one can cut from, and still find plenty of successional bloom, without disfiguring the beds too much. To obtain this, the plants must be well established, the soil well enriched, and a good mulching of manure applied in the winter. For the convenience of gathering the flowers, beds about 1 foot wide, with alleys between, are the best, as if they are put out in large breadths more shoots will get broken down in the constant visiting these beds get during the flowering season than would be got from the alleys if they were all planted. The list of good plants is very numerous, but the following will be found very suitable:—

ACHILLEA PTARMICA, with its innumerable heads or bunches of pretty little double white flowers, keeps on flowering nearly the whole summer, and the more one cuts the more freely does it produce flowering shoots. It spreads freely by means of underground growths that run like Couch Grass, and once established, all the attention it needs is a good mulching of rotten manure in winter and keeping free of weeds in summer; for wreaths it is well adapted, as the flowers, even when dry, look well, being of the nature of Everlastings.

CAMPANULA PERSICIFOLIA FL.-PL. ALBA is a real gem. Its blossoms, if gathered singly and wired, make a good substitute for Gardenias. It spreads freely, and may be increased by division of the roots in winter.

DELPHINIUMS are splendid flowers for cutting, and give a great variety of colour. If the central spikes are cut as soon as the flowers expand, the side shoots spring up and continue a long time, and are really more serviceable than the first bloom. If left to seed, the flowering is soon over. *D. formosum* is easily raised from seed, and makes a fine show with its rich blue spikes of bloom.

HELIANTHUS MULTIFLORUS, or perennial Sun-flower, is one of the best for supplying cut flowers. Once planted, a good top-dressing will keep it right until it requires taking up and dividing, re-planting, if possible, on fresh soil.

THE EVERLASTING PEA (*Lathyrus grandiflorus*).—The red and white-flowered varieties are invaluable for cutting, and if planted near a fence where they can climb over it, they will yield an unfailing supply of bloom, and make beautiful objects as well. They do best if left undisturbed for years. A top-dressing over the crown in winter is all they require.

PYRETHRUMS, single and double, are very beautiful, and they are now of so many varied colours that they are well suited for cutting from. The double whites are especially good. One of the very best of all this useful family is *P. uliginosum*, that comes in late when flowers begin to get scarce out of doors. J. G. H.

Lobelia speciosa Ingrami.—This appears to be the very best of all the pure white forms of *L. speciosa*. It is of a good compact habit of growth,

very free, the flowers large and well formed, and they do not become stained with blue, as is often the case with the white varieties. It will to a considerable extent reproduce itself from seed, but seedlings will be certain to revert to the old blue type. There is no mistaking the seed of a white variety, because it is of a whitish yellow colour, while the seed of the ordinary blue is chestnut-brown. But however carefully the seed may be saved, some blue-flowered varieties will be certain to show themselves. Thus it is that when a good white is obtained, like Messrs. Wood and Ingram's variety, it should be propagated by means of cuttings, and especially so when used for bedding purposes.—R. D.

RAIDS ON WILD FLOWERS.

I WAS pleased to see attention called to this subject as we are in great danger of having many beautiful plants cleared from their native haunts, and in some cases rendered extinct, as these beautiful wildings of the woods have only a brief existence if transferred to the smoky atmosphere of towns. In this locality we have a large vagrant population, half gipsy and half town-bred, that finds a precarious existence by collecting flowers, roots, or whatever they can pick up, and which appears to know the exact localities of any rare hardy plants that are to be found within twenty miles, and the best time for rooting them up. No county in England has more common and crown lands than Hampshire, and while our working population is going to the Far West in search of land to live on, thousands of acres in the New Forest and other parts of this country have never yet had spade or plough put into them, but, in fact, are held sacred to rabbits and Farze bushes, and form a hunting-ground for these wild-flower hawkers. At times these hawkers disappear or migrate for a time (as, for instance, when harvest or hop-picking comes round), but return again to resume their old occupation. The spring is a busy time, and of late there has been an unusual number with baskets and truckloads of roots. Daffodils are dug up just as they show the flower-stems, and later on the bloom is gathered and tied in bunches. Primroses and Snowdrops are treated in the same fashion. Ferns are one of their chief resources, as they are rooted up at all seasons, and may be sold so readily, more especially just as they are unfolding their fronds. Some of the common kinds, such as the Hart's-tongue, increase so rapidly, that little harm is done by thinning them out. But the rarer *Osmunda regalis* is quite exterminated in many woods where it used to be plentiful.

Later in the summer the watercourses afford plenty of blooms of Water Lilies, Bulrushes, &c., that sell readily for room decoration, and some of these collectors go quite twenty miles to get a supply, and cross over from the mainland to search the Isle of Wight for its rich store of floral treasures. Autumn brings Blackberries, and then all hands go picking these, and hundreds of gallons are sold in Portsmouth and the locality, and when these are over the winter is close at hand, and many flock into town again to swell the list of hawkers there, except the more robust ones, who go collecting Briers for Rose stocks, which they dispose of to nurserymen in London and provincial towns. One man told me that he had an order for 30,000 for one London firm, and he in turn employed a lot of other collectors who search the country round for miles. Then Moss, which is hand-picked and tied in bunches, is another thing they get in winter. Of late the fashion of wearing bunches of prettily coloured Ivy leaves that grow wild on trees, fences, &c., has proved quite a boon to these collectors. I presume it is the nature of the soil, for these Ivy leaves are really very pretty, especially in winter, when flowers being scarce they sell readily, and are also used, mixed with Moss, for making up wreaths for funerals, so that with only a few flowers inserted in them they look not only pretty, but are much more durable than if composed of flowers only.

Thus it will be seen that this flower-gathering does some good, but what your correspondents

evidently object to and deplore is the ruthless way in which beautiful trees and shrubs are stripped of their branches and disfigured by well-to-do people who have no excuse for acting in such a senseless and inexcusable way, far less those whom sheer want compels to adopt any safe means of meeting their bare needs of existence. Sundays are the days on which most damage is done to suburban trees, shrubs, and hedgerows, when townstolk flock into the country, and one sees them in the evening returning loaded, and the way they rush into any open gate and snatch off flower or branch has often made me wonder why the contents of gardens are less carefully guarded by the police than the contents of shops, for you will hear people declare that this sort of conduct shows a growing taste for flowers. I must candidly confess that, fond as I am of flowers, I do not wish to see this way of showing increasing regard for them spread any further. A few salutary examples made of flower-destroyers would do a deal of good. It would be a great pity if owners of beautiful parks were compelled to close them on account of the folly of the few, when the majority look on the indulgence shown them with pleasure and enjoy it in a rational way. I have seen many thousands of working people at fêtes and other open-air gatherings in parks and not a twig broken, and when in charge of gardens myself was pleased to see the public admitted on specified days. But sometimes it seems as if a mania for destruction prevailed, as the most unlikely looking people will prove the most ruthless destroyers.—J. G. Haunts.

I am much interested in this subject, and have been engaged for some years in beautifying odd corners, woodland walks, &c., with such plants as are suitable for that purpose. Mr. Coleman's timely article is to the point, and my experience proves that he is perfectly right when he speaks of the ruthless way in which wild flowers are carried off. "J. S. W." does not agree with Mr. Coleman's remarks, but would have the readers of THE GARDEN believe that the inhabitants of the north do not strip the parks or other places of recreation thrown open to them. If this wholesale destruction is not going on, will "J. S. W." tell us what has become of the many British Ferns, &c., that used to be found growing in a great many parts of England? Are they not to be seen exhibited for sale by the London costermonger almost all the year round? If these are not rooted up and carried away from some place where they grow wild, where do they come from, and where are our wild flowers gone to?—G. M. W.

Lilium auratum.—If one year's trial is of any value, I may say that English raised bulbs grown both in pots and in the open ground are far more satisfactory than imported ones. The growth in the second year from a larger number is stronger than I ever had on imported bulbs, and I have not experienced any losses, whereas in the case of imported roots we always lost some. I was, however, somewhat disappointed in the behaviour of the English raised stock, for I fancied that they would come up as strong the second year as they did the first, but they have not done so, and I begin to despair of ever keeping up a stock of this Lily, except by buying every season.—J. C. C.

Seedling Hollyhocks.—Experience in the raising of Hollyhocks from seed has shown that, as a rule, the larger portion come true to the colour of the parent plants. That is the case also when seed is saved from a number of plants of the same colour. I was, however, hardly prepared for such an experience as noted just recently in connection with seedling plants raised under glass from a sowing made at the end of March last. The seed was saved from special plants only, and when the young plants had made strong leafage I found that not only was the distinctive character of each kind strongly marked, but that the foliage of each colour differed distinctly—in one case it was lighter; in another more rounded; in another more woolly—thus giving conclusive proof that Hollyhock flowers, even in plants growing side by side, are not inter-

crossed, and reproduce themselves fully. As a rule, also, the quality or doubleness of the flowers is equally well reproduced, and sometimes even in better form. The knowledge of this fact may perhaps tempt some who admire a fine old garden flower to purchase seed and sow in colours. It is late now to look for bloom from such seedlings this year, but seed may easily be raised in the open ground, and the plants when strong can be dibbled out to where they are to bloom next year. The best preservative from the fungus which still pursues our Hollyhocks is found in deep holding soil partially enriched with manure, and which promotes clean, quick growth. Strong seedlings are less liable to attacks than are older or propagated plants. Once a good stock is obtained, it is easy to save seed from the best and raise plenty of seedling plants every year.—A. D.

DWARF PHLOXES.

THOUGH considerable advances have been made in the improvement of several species of Phlox, much remains to be accomplished by the skillful hybridist to further develop their good properties.

To begin with *P. Drummondii*. What a wealth of beauty awaits the exercise of ordinary intelligence to multiply to an almost unlimited extent even more lovely forms than we at present possess, and how suitable and interesting it would be for ladies and boys to undertake so delightful a task. It may be urged that, being only an annual, its most beautiful seedlings are with difficulty perpetuated, but is not this objection an argument in favour of an attempt to discover a perennial species that will hybridise with it, producing either a fertile race or, if only a barren one, originating perennial and hardy varieties?

Nelsoni well merits attention, as a plate of its seedling varieties published in THE GARDEN shows ample material for still finer productions either by judicious crossing or through the aid of hybridising. *Decussata* and *suffruticosa* are capable of displaying fine properties in addition to those they at present possess. How easily may striped and mottled varieties be originated, adding to our gardens additional charms.

Sterile hybrids can be raised, though with considerable difficulty, by the use of high-coloured *P. Drummondii*, for seed-parents, fertilised with the pollen of crimson, salmon, scarlet, and striped varieties of *decussata* and *suffruticosa*, which hybrids would well repay the nurseryman for his labour.

In conclusion, the difficulties of manipulation named by Henri Lecoq, in his work on "De la Fécondation Naturelle et Artificielle des Vegetaux et de l'Hybridation," are quite imaginary, and it gives me pleasure to be able to assert that the Phlox may be brought as much under the command of the florist as if it were diaceous, and that we ought to depend more on our own resources for novelties rather than trust to Continental seedlings.

An examination of the structure of Phlox flowers shows that its base is so slightly attached to the calyx, that a gentle pull will disengage it even in the bud state, removing the pollen before it can exercise its fertilising influence. By thus preparing the flower the stigma is prematurely exposed; it may, therefore, be wise to keep the seed-bearing plants in pots, so as to be able to remove them from strong sunshine during the hottest part of the day.

A. CLAPHAM.

Mimulus Brilliant.—We have few forms of these beautiful annual *Mimulus*, which give such rich colour as does this variety Brilliant. It is well named, for the flowers, though but medium-sized, are of rich red-maroon, of good form and substance, and profusely borne. Anyone wanting a bed or mass of rich hue in gardens where the soil is holding, will find a bed of this kind easily and cheaply produced. A packet of seed sown in a pan in March, the seedlings when strong enough being dibbled out into other pans, and from these transferred to the open ground in May, gives a glorious mass of rich colour at a very trifling cost. *Mimu-*

luses are fairly hardy, and may be planted out much earlier than ordinary bedding plants.—A. D.

THE NEW HARDY WHITE PASSION FLOWER.
(CONSTANCE ELLIOTT.)

Your plate and description of this semi-novelty (p. 120) direct careful attention to this beautiful variety of an old favourite. Your descriptions are mostly so moderate, exact, and able, that one seldom has occasion to remark upon them. To praise perfection would be presumption; to criticise it would be stupidity; and in this instance it is only an apparent over-estimate of the new form over the old species that calls forth any remark. Your plate and woodcut of the species on the next page place the merits of both well before your readers. But neither these nor the facts as recorded seem to warrant the following sentences in "W. G.'s" otherwise admirable description on pp. 420-21:—

The Constance Elliott variety, moreover, is a vigorous grower and exceptionally floriferous—much more so, in fact, than its parent. In every place where the common Passion flower succeeds, this new white variety will no doubt supplant it, on account of being more attractive in flower and a more delightful garniture for a verandah, alcove, wall, &c.

As to vigour and amount of bloom, it seems physically impossible for the white to excel the blue when the latter is placed in favourable conditions, or, say, the two are placed side by side. After a time the shoots of *P. carulea* look as if they were wholly composed of flower-buds and golden fruits, and it seems impossible for the white to be more floriferous. Enormous differences, however, may be noted between the amount of bloom on blue Passion flowers in different soils and on different sites. The warmer the latter and almost the poorer the former, the more bloom, and *vice versa*.

The other sentence objected to expresses a mere matter of opinion; but it would surely be a misfortune were the new white to supplant the old blue on account of any assumed superiority. How much better to blend the new with the old, as we would probably all agree that the two combined or alternated would have higher decorative merits than either of these colours singly. This would be the more desirable, as "W. G." is silent on the fruiting properties of the Constance Elliott Passion flower. Those most familiar with the decorative value of the old blue will be ready to allow that under glass the rich golden drooping fruits almost match in decorative effects the inimitable grace and maze-like prodigality of greenery and beauty produced by their shootlets, foliage, tendrils, buds, and blossoms. The combined results of all this grace and beauty are so unique and rich, that in this case I would respectfully decline to be off with the old love before being on with the new, and would much prefer to run the two hardy Passion flowers abreast. HORTUS.

SHORT NOTES.—FLOWER.

Passifloras.—Can any of your readers give me the address of any firm, English or Continental, that makes the Passiflora family a speciality? I want to get some of the old species that have ceased to appear in the ordinary nursery catalogues.—J. M. *Charmouth, Dorset.*

Eurybia stellulata is in beautiful bloom now with me against a wall. I would like to photograph it. What a plant to grow in pots for early bloom. *Veronica Girwoodiana* and *Banksian Roses* also beautiful. Daffodils all over, and the foliage getting quite yellow, particularly *Arg-Rich* and *pallidus precox*. This latter dies out in England. They do not know how to grow it. *Capax* is its double form. No doubt of it.—W. B. HARTLAND.

Helleborus viridis.—In THE GARDEN MAY 28 (p. 488) "J. C. B." recommends *Helleborus viridis* as a market plant to be grown for the sake of its winter foliage. The misnomer was probably from inadvertence only on the part of "J.C.B.," but as *H. viridis* has no winter foliage, his advice, if followed, might lead to disappointment. The plant intended is, of course, *Helleborus fetidus*.—T. H. ARCHER-HIND, *South Devon.*

Narcissus incomparabilis semi-partitus.—I am informed that the double form of this *Narcissus* mentioned in THE GARDEN, 21st May (p. 450), is the same as that exhibited by Mr. Ware. Mr. C. R. Scrase-Dickins, the secretary of the *Narcissus* committee, to whom a couple of flowers were sent, says in his reply, "they appear to be precisely similar to those which were shown at the last meeting of the committee."—J. H. KRELAGH, *Hampton.*

Zinnias.—These are splendid annuals for flower-bed decoration in the open air in summer and autumn. They are easily raised from seed, grow freely, and always bloom with great certainty. There are double and single flowering va-

rieties, both of which are very pretty. They grow from 1 foot to 18 inches in height, become bushy, and flower at every point. Plants raised in a frame and planted out in May or early in June will begin to flower in July, and continue to do so until November. I do not know of any class of annuals that present such a beautiful variety of lovely colours as Zinnias.—J. MEIK.

Wild flowers. I have just visited a bleak elevated spot that has so far escaped the hand of the ruthless plant-destroyer one often meets about here with his hamper on his back. On the south-west side of the hill we found in abundance the early *Orehis* of many shades, carpeted with the pretty silvery *Cudweed* and *Bitter Vetch*; these should be seen in masses on a vast open tract to be enjoyed. We saw them with the *Saxifragas* now in flower on the jutting rocks and the gardens of wild golden *Pansies*. Now is the time to look out for the very interesting little *Adder's-tongue* Fern amongst the Grass often on stiff land.—GEO. BOLAS, *North Derbyshire.*

* * Mr. Bolas sends our old friend the mountain *Cudweed*, which is a pretty rock garden and edging plant.—ED.

Crimson Antirrhinums. Last summer when at Wolverhampton I visited the public park there, and was much struck with the effective manner in which Mr. Thomas, the superintendent, had used a remarkably fine strain of crimson *Antirrhinums*. They were in lines as edgings to shrubbery borders, and in groups here and there, and so were seen to the best effect. Mr. Thomas has done much in the way of selecting this particular colour, and I thought it the finest form of a crimson *Antirrhinum* I had ever seen, and it would appear that it comes pretty true from seed. The colour is of a rich blood-crimson, very striking when seen at the close of the day with the setting sun. In the case of a fine variety of this character it is best to propagate it by means of cuttings. In the Tom Thumb section some very fine crimson varieties can also be found. Good self colours are, perhaps, better adapted for decorative purposes than the striped varieties, beautiful as the latter undoubtedly are.—R. D.

Pinguicula grandiflora.—The great Irish *Butterwort* is one of the most handsome plants for bogs at this time of year if well taken care of. It stands the winter very well, being found abundantly in the counties of Cork and Kerry, but during the season is often destroyed by the birds unless protected with netting of some kind. I do not think the birds eat the small bulbs, but the damage done by their becoming exposed is often very great, and is, we believe, a common source of failure. A sure preventive is a small piece of inch wire netting bent over and the ends closed. The display of large blue-purple flowers from a rosette of handsome leaves fully compensates for the little extra trouble required. It prefers a shady spot, but when growing in a well-watered artificial bog, it does very well when fully exposed to the sun. We have found it equally useful as a pot plant; it flowers abundantly, the plants being correspondingly strong and vigorous; others equally useful for the bog are *P. vulgaris*, *P. alpina*, and *P. lusitanica*, the last small, but very pretty.—K.

What is an annual?—In THE GARDEN (page 467) "J. C. C." says that he prefers to treat *Anemone coronaria* as an annual. A friend writing the other day said that he purposed to grow *Primroses* as annuals. There seems to be some incorrect notions as to what constitutes an annual amongst plants, but I always imagined that it comprised those which, sown in the spring, flower, fruit, and die ere the year expires. That section of plants is a large one, and can hardly be mistaken. Some few annuals are so far hardy that they may be sown in the autumn, and standing through the winter will flower early and soon after die. These remain annuals all the same. Biennials, on the other hand, can hardly be classed or treated as annuals, even with artificial treatment. *Wallflowers*, *Brompton Stocks*, *Foxgloves*, *Sweet Williams*, *Canterbury Bells*, are a few of many real biennials, because, sown them as early as we may, they will not bloom till the following year. *Antirrhinums* and *Pentstemons* are both too tender to be treated as biennials, although when so grown produce by far the finest results. They will bloom freely in the autumn,

and if spared by the winter will flower in great profusion and finely in the following summer. Practically, these, with *Hollyhocks*, are biennials. But *Anemone coronaria*, even if sown ever so early in the spring, will not bloom its best until the following spring. The plants, if well done, may carry some straggling flowers late in the autumn, but such blooming does not constitute it an annual; indeed, this *Anemone* can only be fitly described as a perennial, in spite of its few weeks of defoliation in the summer when the tubers are at rest. *Primroses* sown ever so early in the spring in the same way give ever so few flowers that same year, and are not really in bloom till the following March; hence, no form of culture can convert these perennials into annuals. There may not be much in the term "annual," but its frequent use in alliance with certain plants may prove misleading.—A. D.

Narcissus Sir Watkin.—Has "S.W." in THE GARDEN, p. 467, got bulbs of the true variety? I mention this, as I understand a large number of another one has been distributed under this name, or has he got his labels wrong? For why call *Horsfieldi* yellow, it being yellow and white, and perhaps the best of the bicolor section? While to my mind *N. Sir Watkin* is far the best of the selfs, and, taking size of flower, the way it is set upon the footstalk being at such an angle as to admit of its beauty being seen without stooping or turning up the flower, its floriferousness, and, further, its delicious sweetness into consideration, I question if it is not unequalled, and has the good quality of forcing with ease and certainty. The flowers of *N. Horsfieldi* turn almost down, and although large, I have never seen flowers measure 4 inches across; while *N. Sir Watkin* has been measured considerably over 5 inches across, and when planted in a mass is readily distinguishable from all others at a distance of 300 or 400 yards. The leaves of both are exceedingly handsome, those of *N. Sir Watkin* considerably longer, but not so glaucous as *N. Horsfieldi*, as you will see by the few leaves I venture to send by this mail. I have just counted the leaves of what were single bulbs planted in November, 1881, under precisely the same conditions in fairly strong loam with the following results: *N. Horsfieldi* with sixteen and *N. Sir Watkin* with fifty leaves; *N. Horsfieldi* with six flower-stems, while *N. Sir Watkin* with sixteen. J. B. T.

* * The foliage of *N. Horsfieldi* is more obtuse, dwarfed and more glaucous than that of *N. Sir Watkin*, according to the specimens sent by our correspondent.—ED.

PROPAGATING.

GLOXINIAS.—Where *Gloxinias* are raised from seed the earlier ones will by now be commencing to flower, and should any of them be of unusual merit, leaf cuttings may, if desired, be made at once in the manner detailed earlier in the season. Even if the beauty of the plant must not be impaired, a leaf or two can generally be taken off without being observed, and in this way several plants of any particular variety can be obtained without injuring the parent. The leaves, if small, may be dibbled in as other cuttings, while if large they can be cut up into three or four pieces, or, better still, laid on the surface of the soil in a pot or pan, an incision being made through the midrib in two or three places, from whence roots will be produced and young plants in time make their appearance. The leaves must be treated as cuttings of the shoots, viz., kept close in a warm house till rooted.

IVIES.—The propagation of *Ivies* will seem but a very simple matter, yet there are some varieties that do not strike well, more especially the different forms of the *Tree Ivy*. Of the common free-growing kinds, cuttings may be struck in the open ground during the early autumn months, but the more delicate varieties strike far better when protected by a frame, which may often be spared now for such a purpose, and if put in now they soon root. Some of the more delicate kinds are by no means strong growers, and the fact that a cutting, if protected by a frame, need not be above half the length

of one for the open ground is an important item in the case of some of the weaker varieties. Where a considerable number of plants is required, the cuttings may be put in without using pots by just covering the bottom of the frame with drainage material, and over this place about 6 inches of sandy soil sifted fine. This soil having been pressed down tightly and slightly watered will be ready for the reception of the cuttings. They must be dibbled in firmly, and after a thorough watering the lights put on and kept close and shaded from the full rays of the sun till the cuttings are rooted. A length of from 1 inches to 5 inches, or longer if they can be spared, will be a very suitable size, and for the purposes of insertion the bottom leaves must be removed. For such things as these a very good soil is furnished by the refuse of the potting-shed, which generally consists of a mixture of different composts, and if all is passed through a quarter of an inch sieve it may be used for many purposes, this included. The better way to treat the young plants is, as soon as they are rooted, to pot them off and plunge in a sheltered position till spring, when they can be planted out. Of course, before potting them they must be inured to air and sunshine, as if shifted directly from a close and shaded frame to the open air, the effects would be disastrous. Where there are but a few cuttings they may be dibbled into pots, and if kept in a close frame may also be used for striking several things during the summer—viz., many kinds of hardy shrubs, greenhouse plants, soft-wooded subjects, and others. We have an ordinary cold frame set aside for that purpose, and large quantities of different subjects are propagated therein during the summer. Many of the hard-wooded greenhouse plants do better if stood in the frame for a time to allow them to callus, and if placed in a little heat afterwards they soon root. The more delicate Ivies, especially the variegated kinds, are often grafted on strong-growing stocks, which is a much quicker mode of increase than by striking them from cuttings, as they make more progress during their earlier stages. Grafted plants, however, are liable to send up suckers from the bottom, which if not soon removed will rob the graft of its principal nourishment, and to prevent this as far as possible the stocks should, when potted, have all the underground buds removed, for it is far more convenient to have the stocks established in small pots, as they can then readily be placed in a close frame, and space is much economised thereby. Side-grafting is the best for the purpose, and this may be carried out at almost any season of the year, provided the plants are kept close and well shaded till a union is complete, which will be the case in about a month. Provided there is a suitable place for the plants when grafted, no clay or grafting wax will be needed to cover the point of union. The Tree Ivies are the most difficult to root, and they are generally grafted on one of the common kinds.

AZALEAS.—The different Azaleas, including the various forms of *A. indica* and *A. amena*, will, where they have been subjected to an ordinary greenhouse temperature, be in full growth, and just now a favourable opportunity occurs to propagate any that may be required by means of cuttings. The shoots that strike the quickest are those produced in the forcing house early in the season, and at that time instructions were given for their treatment; but these later shoots are by no means difficult to root, provided they are placed under favourable conditions. For cuttings, the side shoots rather than the more stout and vigorous ones should be chosen, and they must be taken off quickly and inserted without delay, as if much exposed they soon flag, and when that happens the chances are that many of them will not strike. If not more than 4 inches or 5 inches long the entire shoot should be taken as a cutting, selecting it at that stage when the very succulent character is just past. The pots for the cuttings must be well drained and filled with very sandy peat, pressed down firmly, with just a little silver sand on the top. Now the propagation of bedding plants is over, there will be more room to spare in some of the cases, and these Azaleas strike best where there is a gentle heat: indeed, a propagating case in the cool end of the stove, or in an

intermediate house, just meets their requirements. If the shoot is cut off cleanly just at its base, and a leaf or two removed, the cutting is complete, and they can then be dibbled in firmly. If a good watering is given, and the pots placed in the case, very little attention will be needed till the plants are rooted, except watering and shading when necessary. Should any signs of decay set in, a little air must be given for an hour or two each day, for if kept too damp a sort of mildew is sometimes liable to attack the bark of the cuttings just level with the surface of the soil, and if not guarded against will sometimes carry off great numbers. If bushy little plants are required, a good plan is to pinch out the top of each shoot as soon as rooted (which will take from six weeks to two months). When the plants recover from this stopping they may at once be potted off, and if kept close in an ordinary cold frame will become well established before winter.

MACKAYA BELLA.—The flowering season of this pretty greenhouse shrub being just over, attention may well be directed to the readiness with which cuttings of it can be struck. The best for this purpose are the young shoots, and if these are taken off and inserted in the ordinary manner they soon strike. To be seen at its best this Mackaya must be grown on rapidly from a cutting till it attains flowering size.

PRIMULA JAPONICA.—As this *Primula* is now in flower a good opportunity occurs to mark the best varieties, if seed of any is required for the purpose of increase. The seed of this should be sown as soon as it is ripe, otherwise it is liable to lie in the ground a very long time before germination takes place, while if sown directly it is gathered the young plants quickly make their appearance. A great many seeds besides these germinate far more quickly if sown as soon as they are gathered. In some cases the difficulty of keeping the young plants of *Primula* through the first winter is a stumbling-block, but, provided they are kept in a cold frame and in rather a dry condition, they will pass through the winter unhurt. T.

ANOTHER PROTEST.

TO THE EDITOR OF THE GARDEN.

SIR,—I can thoroughly sympathise with "E. X.," who describes so graphically the treatment to which he has been subjected by nurserymen, and shall enumerate one or two instances in which I consider I have been somewhat similarly ill-treated in a way that was particularly annoying. The first case was that of a certain *Magnolia* on which I had set my heart, and when going around a nursery with the proprietor I made known to him my wants, and inquired could he supply me with the required article? He said at the moment he was sold out of that variety, but expected a consignment in a short time from the Continent, and at the same time he strongly recommended a certain other variety as a much better one than what I required. But as I knew both varieties, and also naturally knew what I wanted better than he could be expected to do, I declined to take the plant pointed out to me. Thus the matter remained until the following year, when I wrote to the same nursery for my longed-for *Magnolia*, and in reply had the very plant which a year before I had refused to take packed off to me. I was so annoyed at this impertinence that I at once sent back the plant, and along with it a letter of indignant remonstrance at such treatment. The next instance was that of some specially-selected shades of *Clematis* of the *lauguosa* type, which I required for planting out in a conservatory, and for which I wrote to another nursery. As the proprietor did not happen to have them in stock, he coolly substituted other varieties, saying he was quite sure I would find those sent would suit my purpose, and that they were newer and better varieties. Need I say these plants also had to undergo the fatigue of a return journey.

Then, as to the number nuisance, I would say it is sometimes rather irritating, for I have at the present moment in one of the houses several plants, under numbers only, which I wrote for two years

ago, having got the names out of a catalogue which was lent to me for a day or two, and as the plants came to hand with only a number affixed, thus they remain, as I had no means of knowing which they were without writing again to the nursery for a catalogue. In one case I had to write to a foreign country again, as the plants sent from a nursery there under numbers appeared in the catalogue with the names only.

Lastly, as to the compensation-for-carriage nuisance, I find that the plants which are most frequently sent to me for that generous purpose are such choice subjects as the *Winter Heliotrope* and *Anemone japonica*, the former an insidious pest I have in vain tried to eradicate, and the latter a plant I would willingly give my benefactor a bushel of if he would kindly relieve me of its unwelcome presence. How much simpler for the nurseryman to add a duplicate of some plant ordered than to rack his brain at a busy season to try and find out the supposed wants of his victim.—ONE OF THE INJURED.

— I wish to join in the protest with "E. X." (p. 473), and to supplement his remarks with one other. I protest against nurserymen putting into their catalogues the names of plants they have not got. I have frequently sent for a perhaps not very common plant, and added a few others to make up an order, not caring to send for a single plant. I receive all but the only one I really want with the remark, "Regret so-and-so is not in stock." Ought this so to be?—A. R.

GARDEN FLORA.

PLATE 599.

HERBACEOUS PÆONIES.

(WITH A COLOURED PLATE OF *P. DECORA ELATIO*, *LOBATA*, AND *ANEMONÆFLORA*.)

CULTIVATORS of hardy plants should not be slow in adding as many of these charming plants to their collections as they can gather together, as not only are they the most handsome and striking amongst outdoor flowers at the present time, but their amenity to ordinary garden soil gives the grower no excuse at all for their exclusion. Shade as well as full sunshine seem to bring out the natural beauty of these flowers. We have seen them in the wood, or on the border of the little brook shedding a rare splendour along its banks, and giving the *Pæony* a character we rarely see when grown in the ordinary flower border. The great secret in growing *Pæonies* successfully is no doubt a good supply of water during the growing season, with liquid manure at intervals. As they are gross feeders, our plan is to mulch heavily early in spring, just as the young shoots are beginning to peep above ground, keeping them well watered at intervals during the summer months; indeed, the most robust plants we ever saw were in such a low position as to allow of their being deluged with sewerage water at regular intervals. One thing to be guarded against, especially with the European species and officialis in particular, is deep planting, as if planted too deeply they are apt to rot even after having grown 6 inches or more above ground. *Pæonies*, as a general rule, are so easily increased, either by division or seed, that there is no excuse for their scarcity in gardens where there is plenty of space that can be devoted to their cultivation. Where opportunity offers they should be largely planted in the park, semi-wild parts, by the woodland walks, &c. The effect of a group of these, well clothed with elegant foliage and surmounted by their numerous large, handsome, variously-coloured flowers, is very fine, and has only to be seen to be generally adopted. Even when grown in full

shade the colours are very bright, and, being a fortnight or so later, succeed those in the open.

The following are short descriptions of those figured on the annexed plate, a description of the albiflora section having been given, with a plate of Adrian, a few months ago:—

P. DECORA.—This is a very handsome species, and, as Anderson remarks, well marked out from all the others by the elegant stateliness of its habit; each stalk accompanied by its horizontal leaves diminishing as they ascend, and terminated by its

Peonia sinensis (P. albiflora).

flower, supported on a long peduncle, exhibits somewhat of a pyramidal figure. It is clearly allied to *P. arietina*, although when seen growing side by side with that species the distinction is wide enough for all practical purposes. In *P. decora* the leaflets are tripartite, narrow, oblong, blunt, and hairy underneath; flowers medium-sized, purple, red, or crimson. *P. d. var. elatior*, well represented in the accompanying plate, is also one of the varieties described by Anderson. It was first seen in Messrs. Chandler and Buckingham's nursery, and was believed to have been introduced from Holland. The leaves are much broader than in the type, the plant altogether more robust in habit and more hairy.

P. D. VAR. PALLASI has narrow, oblong leaflets, flowers very large and open, not unlike a large Poppy, deep rich crimson, changing to a bright rose as it fades. It was first introduced by Messrs. Lee and Kennedy, who received the seed from Pallas.

P. LOBATA (a coloured illustration of which will be found on the annexed plate) has been placed as a variety under *P. officinalis* by Mr. Baker. It is, however, perfectly distinct as a garden plant, not only in its dwarfer habit, its narrower and more numerous leaflets, but also in the very unusual colour of its charming flowers. It forms an erect little bush about 18 inches high, the leaves much divided, and slightly hairy underneath. It produces numerous cup-shaped flowers, pale rose-red, with a tinge of yellow—a very unusual colour in a flower, on which account it is very interesting. It grows freely in ordinary garden soil, and we have found it very useful for the rockery, in the spring displaying its purple stems and flowers, and all through the summer and early autumn its handsome foliage.

P. OFFICINALIS AND ITS VARIETIES.

The numerous florists' *Pæonies* we possess at the present time, excluding of course *P. Moutan* and its varieties, have nearly all been derived from the variable Chinese *P. albiflora*, a species extremely fertile in variety of form and no less so in range of colour, almost every conceivable shade of rose, crimson, pink, &c.,

as well as many shades of white, being abundantly represented. Many of them are very fragrant, and in some few we have a very good imitation of the Rose. Although both numerous and variable, it is very questionable if they are so widely circulated in the old hardy flower gardens as the old European *P. officinalis* and its varieties, a half dozen or so being cultivated at present, and have been common, we are told, in almost every cottage garden in England since about 1580. There can be very little doubt now that the double forms of this species are the same as those spoken of by the old writers, large clumps of many of which may be seen even now in the places that escaped the general destruction of good old plants caused by the bedding mania.

P. OFFICINALIS, the type, is perhaps not so common in gardens as it might be; it is not so striking as the varieties, but it has a grace of its own that entitles it to a place amongst all old flowers. It grows between 2 feet and 3 feet high, stems stout and one-flowered. The flowers are dark crimson, overlapping one another, and nearly orbicular in form; leaves oblong, narrow, and pointed, dark green above, and generally very pale underneath. It begins to flower about the middle of May. It is a native of Southern Europe, and said by Turner to have been grown in our gardens as early as 1562.

P. O. ANEMONÆFLORA (see the accompanying plate) is a handsome flower, crimson shaded magenta, and slightly flaked with purple. There is also a double form, very desirable, with irregular petals, not unlike a double Anemone, but twice the size.

P. O. ALBICANS (the old double white of gardens) is first recorded by Tabernaemontanus in 1590, and must have come into cultivation about the same time as the double red. The flowers when first open are of a delicate pale pink, and as they become older are almost white; it is not so free as the red-flowered one, but will be found a useful companion and a first-rate plant for rockery or woodland walks, &c., where it attains extraordinary dimensions.

Peonia tentifolia.

P. O. VAR. BLANDA.—The leaflets of this variety are somewhat narrower than in *rosea*, the margins less undulated, and of an uncommon light green colour, rarely, if ever, seen in the typical plant; the habit is much more spreading than in the variety *rosea*, flower-stems reddish, flowers blush-coloured, very striking and fine.

P. O. VAR. CARNESCENS (the double flesh-coloured *Pæony*).—This is perhaps, with the exception of *anemonæflora*, the newest form of the group described

here, having first been recorded by Morrison about 1699; on first opening the flowers are of a fine rose colour, and as they advance become pale flesh-coloured. It is a charming plant, and should be in every garden as a companion to the double red, flowering as it does about the same time.

P. O. VAR. ROSEA.—This handsome variety is said to have been found by Mr. Sabine, along with *blanda*, in the Oxford Botanic Garden, but no account of their history previous to this has been recorded; they are supposed to have both been there for a considerable time previously. The leaves of *rosea* are very large, leaflets broad and undulated, blunt, very dark green, and often tinged with red on the margins; the prominent ribs on the under surface of the leaflets are sparingly covered with longish hairs; flowers of a beautiful rose colour, produced about a fortnight earlier than those of *P. Sabini*, in ordinary seasons about the middle of May.

P. O. VAR. RUBRA.—This is no doubt the old double red of gardens, the first account of which we have in Lobel's "Icones," 1581. The grand double *Pæonies* from China, magnificently rich and striking as they are, cannot be compared with this common denizen of our old gardens. It has long held the first place amongst hardy border plants, and is likely to do so, notwithstanding the tendency of fashion for single flowers. The flowers are rich crimson, very large, and produced in the greatest profusion, lasting a considerable time in their full glory.

P. O. VAR. SABINI.—It appears that a few years previous to Anderson's "Monograph of the *Pæonias*," in the 12th number of the Linnean Transactions, the single-flowered *P. officinalis* had become so rare in gardens, that it was scarcely known to writers of that period; in fact, a single-flowered form was not believed to exist in a living state until Mr. Sabine had the fortune to find a plant in the corner of an obscure old garden in Hertfordshire. It differs but slightly from the type, the flowers exactly corresponding in colour to those of the double red, opening a few days earlier, and not lasting nearly so long in bloom; the leaves are much less undulated than the type, the plant being more robust in habit. The above represent two sections of this charming genus, *officinalis* and *lobata* representing the section to which *tentifolia*, *anomala*, *Emodi*, *peregrina*, *mollis*, and *paradoxa* belong, and *decora* representing *corallina*, *Russi*, *Broteri*, *triternata* (*daurica*), *cretica*, and *arietina*—all sufficiently distinct and handsome as to make them a desideratum of every grower who has space at his disposal.

D. K.

STOVE AND GREENHOUSE.

T. BAINES.

AOTUS GRACILLIMA.

IN this we have one of the numerous hard-wooded New Holland plants that was extensively grown for some time after its introduction, but which has given place to things that can be cultivated with a minimum amount of skill and attention, and which are quickly got up from the seed-pan, or cutting-pot, to a flowering state. For some time after this *Aotus* made its appearance it was often met with in competing groups at exhibitions; so used, when represented by a well-managed specimen, its distinct habit of growth seldom failed to make it an object of interest; but its pretty, small, pea-shaped red and yellow flowers, though produced in such profusion as to literally crowd the thread-like shoots to an extent that is seen in few other things, are not so showy as those of many plants that come from the same part of the world, hence it is now rarely seen on the exhibition stage. The extremely elegant habit which it possesses is not the least of its merits. In fact it would be difficult to find amongst all the plants that are subject to pot culture any that surpass it in this respect. When strong and in good condition, the annual shoots are from 2 feet to 2½ feet in length, though no thicker than fine whip-cord; they are clothed with long, very narrow leaves, and droop much in the way of a Kilmar-

noek Willow. To this drooping habit the plant owes much of its distinct and elegant appearance. Although by no means a plant of strong and vigorous habit, it nevertheless grows much more freely than the generality of hard-wooded species, and is less liable to get out of order unless subjected to neglect; with ordinary care it will continue to thrive for a long time. This combined with its distinct character makes it a desirable plant for greenhouse decoration, where, to those who appreciate elegance of habit, even when out of flower, it is attractive. It can be easily struck from cuttings, which if taken off when the growth is half matured in the latter part of summer seldom fail to root. The cuttings should consist of the points of the shoots about 2 inches long, and may be put 1 inch apart in 5-inch or 6-inch pots filled with sand; cover with a propagating glass, and keep the sand moderately moist. Stand them in a greenhouse and shade from the sun until their base is callused, then remove them to a house or pit where a moderate amount of heat is kept up, and during the winter they will make roots. In spring put them singly in small pots, using good fibrous peat, adding a moderate quantity of sand; it will be best to sift the peat whilst the plants are small. Keep in an intermediate temperature, standing the pots on material that will hold a little moisture. Give a thin shade in bright weather, but plenty of light, admit a moderate amount of air, and sprinkle overhead with the syringe daily. Treated in this way the little plants will make progress. From the decided inclination which the shoots of this *Aotus* have to droop it is better to grow it in the form of low standards about 15 inches or 18 inches high; consequently the leading shoots should not be stopped in the manner usually done with plants of more erect habit. Instead of this secure each to a thin stick until the requisite height is attained, after which pinch out the points to induce them to branch out.

During the summer it will be necessary to give a shift. Four-inch pots will be about the right size. Use sifted peat similar to that in which the little plants were first placed. After this second potting, continue to keep in a genial growing temperature until the roots have taken to the new soil; when more air may be given, discontinue the use of fire-heat, and cease shading and syringing. Through the winter a temperature of about 15° in the night should be kept up, as young stock of this, as of most other plants that come from the same part of the world, do not move so freely when the spring comes round if allowed to be too cold in winter. In the spring a little before the growth begins, cut the shoots back to within about 2 inches of where they spring, and as soon as the young growth is moving freely, give pots two sizes larger. Now use the peat unsifted; pot moderately firm, and keep the atmosphere somewhat close for two or three weeks until the roots begin to enter the new soil. Shade when the weather is bright, and encourage growth through the summer by keeping the material on which the pots are stood and the floor moist. Syringe in the afternoons when the house is closed, which should be done early enough to shut in the sun-heat that is so important an agent in helping the free development of the shoots. There must be no attempt at shoot-stopping in the way usually practised with most hard-wooded subjects, farther than if there happens to be odd branches that take an undue lead so as to outgrow the remainder, they may have their points pinched out; but whatever requires doing in this respect must be attended to early in the season, otherwise the requisite balance in the strength of the shoots will not be secured. All in the way of stakes and ties that will be required by the plants, or, in fact, that is admissible, is a stick to support the main stem, leaving the branches to assume their natural drooping form. Winter as before. As already said, this *Aotus* is a very free bloomer, so that if all goes well, the little plants may be expected to flower in May. Even in this small state they are effective. Whilst in bloom keep them cool and shaded from the sun, so as to prolong the flowering period. After the bloom has faded shorten the shoots back to within 2 inches of where they were cut to last year, and encourage the plants

to break by syringing and keeping them in a growing temperature. When they have broken and the young shoots are an inch or two long, move into pots about two sizes larger than those they have already occupied; treat as advised for the preceding summer, and winter as before. Again in spring after they have bloomed, shorten the shoots, and give additional root-room as required. By following this treatment the plants may be expected to last for many years, increasing in size and in their annual display of bloom. Though, as already said, this *Aotus* is wanting in the showy appearance of its flowers individually, it is always effective; even when out of bloom its slender, pendulous shoots afford a contrast to everything else with which it may happen to be associated.

I have hitherto said nothing about its requirements in respect to water; although, in common with other hard-wooded greenhouse species, it will not bear neglect in this matter, yet it is by no means a ticklish subject to deal with, provided the two extremes of allowing the soil to get unreasonably dry or of saturating it with water are avoided. With fair attention it seldom gets out of condition.

A climber from Nice.—You would kindly oblige me in naming the climbing plant sent herewith. It is a very large creeper; the tree it strangles is quite overhung with its golden garlands. I send also a very bad photograph of a flowering *Dorvanthes* (?)—flower brilliant scarlet without, white inside. I hope to send you a better one soon.

E. KORSCHGREY, *Villa Montharon, Nice.*

** The strangler is a very beautiful one—*Bignonia*.—ED.

Vitis heterophylla variegata.—This slender growing Vine is occasionally seen bedded out during the summer months, but perhaps the most useful purpose to which it can be applied is as a foliage plant grown into neat little specimens and kept under glass. If stopped once or twice during its earlier stages and secured to a single stick it will assume somewhat of a pyramidal habit, and is then very useful for a variety of purposes. The variegation of the foliage is most irregular, some leaves being nearly all green, but most of them are beautifully mottled and marked in different ways with white, many of the younger ones being almost entirely of this latter hue, while the bark of the young shoots being of a pleasing shade of purplish pink is conspicuous against the light-coloured foliage. This Vine is, like the rest of its class, deciduous, and may be kept in a dormant condition in the greenhouse during the winter, and if started in a gentle heat in early spring will soon be in full leaf. Propagation is effected by means of the young shoots, that strike readily enough if taken off at a joint, and dibbled into pots of sandy soil and placed in a propagating case soon form roots. H. P.

Sea sand for plants.—There seems a great diversity of opinion about using sea sand for plants, yet I have used it for all purposes for which sand is required. I never take the trouble to wash it, but use it just as it comes from the coast with the water dripping out of it. In the autumn of 1884 I had a lot of seedling *Cinerarias* planted under a north wall, in about one-half sea sand and burnt earth on a solid clay foundation. They were put there in the early part of the summer, being the surplus of what I had after potting off the seedlings. They grew very strongly, and after throwing away a lot of *Coluses* in autumn I lifted about four dozen, and as a load of sand was received on the same day, I used the wet sand to mix with the potting soil. I potted them into this mixture, and I never saw a finer lot of plants. They were put into 8-inch pots and afterwards into 10-inch and 12-inch pots. The leaves resembled those of *Blubarb*, and the heads of bloom were nearly 3 feet across, and would have been more if they had been tied out. Being only a mile from the beach, it only costs 2s. per load, and I have used over a dozen loads to dig into flower borders to lighten them, and as the soil was very heavy I used it in summer when bedding out. I put sand all round *Iresines*, *Lobelias*, and all fine-rooting bedding plants. I also used it

to strike cuttings of all greenhouse stuff, and for striking *Iresines* and *Coluses* nothing is better. I used about half sand and half *Cocoa* fibre. I have also grown *Gloxinias* and *Begonias* in it. I see "J. M., Charnouth, Dorset," says that it killed a lot of his plants, but, except two or three *Coluses* and about half a dozen other miscellaneous plants, I never lost any. When I examined those that died with me I found that they were all water-logged, so that I could not say whether it was the fault of the sand or the careless watering. I trust other correspondents will give their experience, as I think many do not use it because they are afraid it will do harm. When at Messrs. Cunnell's at Swanley the other day I saw a lot of it, and they say they always use it.—NEMO.

GREENHOUSE RHODODENDRONS.

THESE are by no means common, as many gardens may be visited without finding one of them; they are, nevertheless, showy plants, and should be grown in every greenhouse. *Azaleas* are noted for their attractive flowers, but these *Rhododendrons* are far in advance of the best of the *Azaleas* in the beauty of their chaste and gorgeous blossoms, and the delicious fragrance of many of the *Rhododendron* flowers is not excelled by any other flower in the garden. When in bloom about Easter and Whitsuntide they are very beautiful. I am greatly astonished that they are not more plentiful, as there is much space and attention given to many plants not one quarter so valuable. If all who take an interest in the highest classes of greenhouse flowers would obtain half-a-dozen of these *Rhododendrons* and see them bloom once, large additions would soon be made to their stock, as it is impossible to over-estimate their merits. The following are all charming sorts: *R. fragrantissimum*, flowers pure white, deliciously fragrant; *R. Pink Beauty*, flowers of a delicate pink colour; *R. fulgens*, fiery crimson, compact growth, very effective; *R. Countess of Haddington*, large bluish white flowers; *R. Daviesi*, magnificent flowers of a bright orange-red colour; *R. jasmiflorum*, very free blooming, white, fragrant, excellent for bouquet-making; *R. Jenkinsi*, flowers very large, funnel-shaped, snowy white, very beautiful; *R. Rosalind*, compact habit, delicate pink flowers, charming. There are many others equally good, but the above would readily give so much satisfaction to anyone as to fully establish greenhouse *Rhododendrons* in their favour. They may all be grown very successfully in pots. Now is the time to repot them. Do not give them too much root room, but they may always be safely transferred into pots 2 inches larger than those they previously occupied. They do not require to be potted every year, and if carefully potted now they may not require this attention again for two or three years. The pots cannot be too carefully drained. The potting mixture should consist of two parts peat, one of loam, and one of sand. When the plants are turned out of their pots every particle of the loose soil that does not contain any roots should be removed, but the roots must not be broken. Pot very firmly, ramming the soil all round carefully with a blunt-pointed stick. Use the soil moderately dry and water thoroughly soon afterwards. As soon as potted it is important that the roots and shoots make free growth, and to assist them in this, place them in a moist atmosphere where the temperature is about 70°. Ainery not too far advanced is a good place for them, as they are benefited by a little shade at first and until the growths have developed considerably, but they should be well exposed to the sun and air when the buds begin to form, and during the autumn months they should be placed in the open air altogether, the main points necessary to secure abundance of bloom being a luxuriant growth in the first place, and a thorough ripening of the wood afterwards. Badly-ripened wood will never produce many or good blooms. The foliage is apt to harbour insects at times, but a free use of the syringe when the plants are making their growth will, as a rule, keep them clean and healthy. CAMBRIAN.

Sweet-scented Rhododendrons.—A great many greenhouse *Rhododendrons* have their blo-

soms more or less scented, but those in which that character is the most pronounced are a few hybrid varieties claiming parentage either from *R. ciliatum* or *R. Edgeworthi*. The progeny of this last are all remarkable for the fragrance of their blossoms, and include among their number *R. Princess Alice*, the result of a cross between *R. ciliatum* and *Edgeworthi*; *Sesterianum*, between this last and *R. formosum* or *Gibsoni*. A great many varieties raised between *R. Edgeworthi* and the twiggy growing *R. multiflorum* are as remarkable for the fragrance of their blossoms as for their free-flowering qualities. The hybrids raised from *R. Veitchianum*, beautiful though they be, are not so fragrant as those above mentioned. With regard to the beauty of its blossoms, this species (*R. Veitchianum*) is surpassed by none, as in the best variety the blooms are large, very wax-like in texture, and pure white in colour, except a yellowish blotch at the base of the upper petal. The edges of the flowers, too, are beautifully crimped. In this respect they vary greatly; indeed, there is a variety (*laevigatum*) with the edges of the petals smooth, but it is not so attractive a flower as the other. Seedlings of these different *Rhododendrons* vary considerably in their ornamental qualities, some being in this respect much superior to others, so that in order to increase the finest type it is necessary to propagate it by cuttings or grafts. H. P.

Lemon-scented Verbena. This is a favourite plant with many. It is frequently grown in pots, and a few specimens of it are very useful in the greenhouse, and it also succeeds well in the open air in summer. It should be planted against a wall or in a very sheltered sunny position. I know of several large wall specimens which have been cut down lately or during the last winter by the frost, and as it is not quite hardy it should be protected when left out all winter, but although some of the branches may appear dead—in fact, may be quite dead—for a considerable distance down, the roots are more difficult to kill, and the plants should never be thrown away as dead in spring until they fail to show life in summer.—J. MURR.

Capsicums and Chillies.—It seems strange at a time when ornamental fruit-bearing plants are so much sought after that these are so little cultivated in this country. In scarcely one garden in twenty, with abundance of glass, is little or any attention devoted to these truly ornamental, as well as useful, plants. They were more generally grown by the old gardeners, and even within living memory most gardens with a few frames contained some pots of Capsicums, and nice specimens they frequently were. They well repay a little extra care. I suppose novelties have thrust them aside. A spur would be put to their popularity if at flower shows prizes were offered for, say, twelve pots of not less than six kinds. I submit this to the committees of horticultural exhibitions; I am sure it would be an interesting and attractive feature. In America, where they are largely grown, many varieties are obtainable, yielding fruits varying in size from a large barley-corn up to a goose's egg, crimson, scarlet, yellow, and bi-coloured, but I always think the reds most attractive; it is, however, perhaps a matter of taste. I apprehend that, although treated as annuals, most or all are perennials in the Tropics. I have kept them for three years, and generally keep them over the second, the advantage of which is their fruiting so much earlier. Such plants I have now with half-grown fruit on them, while this year's seedlings are not even yet showing bloom. Of course, they can only be wintered in a stove, but everyone possessing such a structure should find room for a few specimens, and their sight will be gratified with the handsome fruits for months.—J. M., *Charmouth, Dorset*.

Manure water for Camellias.—On reading the article in THE GARDEN (p. 462) on "Manure water for Camellias," by "Hortus," it brought to mind a few facts in my own experience in this matter. Upon taking charge of the gardens belonging to a gentleman in the midland counties some years ago, I found in the collection of plants a *Camellia reticulata*. This was thought a good deal of by my employer, and I was told that it had

produced "four large flowers all open at the same time." I was rather amused at the statement, but said nothing, as it was very plain that the plant could be made to produce better results. It was a lanky, straggling plant, and the first thing I did was to take out the terminal buds in order to get shoots to break from the old wood. It was very much pot-bound, but I determined not to repot it, but see what could be done by the use of stimulating food in the form of liquid manure. The way I made this was by pouring large quantities of water upon the manure in the stable manure pit, and allowing the liquid to flow into a catch-pit outside. This was used diluted with water at a strength of about one gallon to four of water, and the plant was always watered with this when dry till its growth was completed. It threw out shoots from the old wood even beyond my expectations, and in the course of three or four years became a well furnished plant, and instead of producing four blooms "all open at the same time," there were two dozen all open at once. I believe that many *Camellias* are ruined from overpotting and subsequent injudicious watering.—R. LLOYD, *Brookwood*.

THE CALCEOLARIA.

Those of us who can look back over a period of but thirty years can contemplate with satisfaction the great improvement made in that time in this very showy greenhouse plant. At that time Mr. Kinghorn, now of Sheen Nursery, Richmond, was an industrious raiser of new varieties, and sent out many which were great improvements on the old forms, under name, for at that time when a distinct and good variety was produced it was propagated at once by division of the plant, and a good stock was obtained the first season. Another very intelligent cultivator was Mr. Joseph Plant, of Choadle, in Staffordshire; he was also a raiser of seedling forms, and produced a type with distinctly striped flowers, but at that time the plant grew very tall and the striped varieties were no exception. In Scotland the prevailing type had golden yellow flowers of excellent form, densely spotted with red, crimson, or maroon. There were also seeds of many colours which have been improved through successive seasons, until the latest improvements exhibited at the recent flower shows, notably by Mr. James, of Farham Royal, have eclipsed anything hitherto seen in cultivation. It is not to be expected that improvement can go on so rapidly in the future as it has done in the past, nor does it seem to be necessary, as the standard of perfection has almost been attained. The plants now in cultivation are of dwarf, compact habit. The heads of bloom are very large, and the flowers possess the requisite properties of good form, size, richness, and diversity of colouring. The set of twelve plants which was awarded the first prize at the Crystal Palace contained the best examples of culture ever seen in London. The individual specimens were of large size, and the well-formed, richly coloured flowers were $2\frac{1}{2}$ inches in diameter. One had flowers of a rich deep yellow, densely dotted and spotted cinnamon-red; others yellow, blotched maroon; primrose, lightly spotted crimson; yellow, sparingly spotted with red; crimson-scarlet, and yellow self-coloured flowers. How are such handsome specimens produced? is a question many persons have asked. In the first place, a good strain of seeds must be obtained. Mr. James has, by careful selection through a long series of years, brought the *Calceolaria* to its present state of excellence. He also has a thorough knowledge of the requirements of his plants. The seeds may be sown now or in June and July; they are of very small size, and a packet obtained from the seed shops is so minute, that a careless person, in opening the packet, has jerked all the seeds out of it, and innocently insisted that it never contained any. A 5-inch pot is the right size for an ordinary half-crown packet of seeds. The pot should be well drained, and filled to within an inch of the rim with ordinary potting soil. The half-inch on the top must be finished up with finely-sifted sandy soil and made quite level; on this sow the seeds, and just sprinkle over them some

fine sand. It is a good plan to lay a square of glass over the top to keep the soil in a moist condition, for if it should become over dry during the germination of the seeds, probably the whole of them would perish. I generally place the pot containing the seeds in a hand-glass or frame, on the north side of a wall or fence, to prevent any injury from the action of the sun. When the tiny seedlings are large enough to be pricked out, a dozen of them may be planted in a 3-inch pot, and when the leaves of these pretty well cover the surface they may again be potted off, three into the same sized pot, to be again repotted with one in a pot. After this they grow very freely when the conditions are favourable to their perfect development; and those conditions are, first, good potting soil, composed of three parts good turfy loam, one part leaf-mould, one part decayed stable manure, and a little turfy peat. The plants must also be kept steadily growing in a greenhouse, kept close to the glass, and shaded lightly from the mid-day sun. The plants must be repotted before they become in the least root-bound. They like ample ventilation, but if the wind is high and dry the ventilators must not be opened on that side from which the wind blows, as a high, drying wind causes the leaves to flag as if the plants were suffering from want of water. This is another thing that must not happen, because a plant that suffers from over-dryness once will never make such a perfect specimen as if this had not taken place; but if this should occur more than once, the probability of successful results is very remote. Further, any plants that receive a check to their growth are almost sure to become infested with green-fly sooner than those that are kept in a healthy growing state. In fact, it must be noted here that no plant is more liable to be attacked by green-fly, which would render the plants worthless if not constantly destroyed by fumigating with Tobacco smoke. Besides the raising of plants from seeds, they can readily be propagated from rooted offsets. These are obtained by placing the plants when they are past flowering into a cool pit or frame; some good compost may be placed over the bare stems, and roots will speedily push out from the part of the stem nearest the leaves. Whenever these roots are formed the plants may be divided, and the small portions be repotted into 3-inch or 1-inch pots. At one time nearly all the plants grown in gardens were propagated in this way, but they are not so free in growth, nor do they make such handsome specimens as seedlings do.

J. DOUGLAS.

Bossiaea linophylla.—This is a pretty plant, belonging to the Leguminosae family, and is remarkable alike for its grace and elegance as for its profusion of blossoms. It is of very slender habit, and is seen to the greatest advantage in the shape of a good-sized specimen, with the centre branches secured to a stake and the others allowed to hang down naturally. In this way the lesser shoots will droop as much as those of the Weeping Willow, and will be now clothed for the greater part of their length with bloom. The individual flowers are Pea-shaped, rather small, and of a bright orange colour. The leaves are narrow, and by no means densely arranged on the branches. This *Bossiaea* is a native of South-west Australia, and the treatment usually accorded to *Chorozemas* and similar subjects will suit it perfectly. Cuttings are by no means easy to strike, but as a set-off to this seeds may often be obtained.—H. P.

Kennedyia Murrayatae.—One great merit is certainly possessed by this beautiful greenhouse climber, viz., that of continuous flowering, for, provided the roots are in a healthy condition and not too much restricted, it will grow and flower nearly all the year. It is certainly a climber that should be made a note of where a selection of these plants is required, for, in addition to its free-flowering quality, it is altogether of easy culture. Cuttings are not difficult to strike if formed of the young shoots at this season, selecting for the purpose those with short joints rather than the more vigorous ones. Seeds, too, often ripen, and though plants raised from cuttings are more floriferous in their

earlier stages, seedlings, generally speaking, grow more quickly, which last is an advantage in the case of a climbing plant. If in rather a hot situation near the roof, a liberal use of the syringe will be necessary to keep down red spider, which, once they effect a lodgment on the foliage, are difficult to eradicate.—H. P.

SEASONABLE WORK IN PLANT HOUSES.

STOVE.—CLERODENDRON BALFOURI.—The value of this *Clerodendron* for decoration can scarcely be overrated, especially when the length of time during which, with a sufficient number of plants, a succession of its flowers can be had is taken into account. By starting some early in the year, with others to follow, it may be had in bloom from the beginning of April up to the latter part of summer. Moderate-sized examples, such as can be grown in 13-inch or 14-inch pots, are the most useful. A well-managed plant in a pot of this size will produce a large quantity of flowers. It is an easy matter to confine the specimens to this size, as the plant will bear cutting closely in after flowering and much of the old soil being shaken away. By this means new material can be given it annually. Plants of the size named, as they go out of flower, may have their shoots cut back to within 4 inches or 5 inches of the base. This *Clerodendron* is a remarkably free grower. If after being shortened back it is placed in moderate stove heat and syringed overhead daily, it will break in a fortnight, when the plants should be turned out of the pots and have a good portion of the old soil removed. Such as are in pots of the size above named, and that are required to be kept in this size, may have half or more of the old material taken away, removing the long straggling roots that will have found their way down to the drainage. Repot in good turfy loam, to which add about one-fifth of rotten manure and some sand; pot firmly, and stand them in a house or light pit where a free growing temperature is maintained. The young shoots should be trained to thin strings, secured to the roof in a way that will keep their points upward. If a sufficient number of shoots is present, there must be no attempt at stopping, as, if the plants are strong, it is more likely that they will require reducing. Examples of the size named are better with about fourteen or fifteen strong growths than if consisting of more and weaker. The object is to get them as strong as possible, with the wood hard and short-jointed. To secure this they must be kept close to the glass, and as soon as the roots have got fairly hold give manure water every other time the soil requires moistening. Admit a moderate amount of air in the middle of the day, and syringe freely at closing time. By following this course as the plants go out of flower with half a dozen specimens, a lengthened succession of flowers may be relied on next year.

IXORAS.—Where there is a regular demand for choice cut flowers there are few things that are more useful than *Ixoras*, provided the plants are well grown. If in indifferent condition they are of little use, as in place of blooming more or less through the autumn season, as *I. coccinea* will when well cared for, and giving separate crops of flowers, as most of the seedling varieties do, they make only a meagre display for a short time in the summer. The essentials to success are a good light house to grow them in, with sufficient heating power to keep the temperature well up in winter, no stint of pot room and regular attention in keeping down insects, which, if once they get a footing, increase apace. In respect to re-potting, it is not well to confine the operation to some particular period, such as often practised with plants of many kinds. If several small examples of the same kind of *Ixora*, all of one age and alike in condition, are taken in hand, it will almost invariably be found that some will outgrow the others to an extent that does not usually occur with most things. This is more apparent in *I. coccinea* than any of the other species or in the numerous hybrids now in cultivation; when it happens either with young plants or others that have attained more size, but are not fully grown specimens, more room should at once be given, as if the roots get pot-bound the growth immediately feels

the effects by becoming weak and stunted, in which case it is difficult to afterwards get the plants to move freely. To grow *Ixoras* successfully they require to be pushed along during the early stages of their existence, giving them larger pots proportionate to the size they attain than almost any other stove flowering plant with which I am acquainted. The present is a good time to shift any that need it, as there is plenty of time for the roots to get fully hold of the soil; this they will do even much later on than this, provided enough warmth is given them during the autumn. The best fibrous peat with a moderate addition of sand is the only material I should care to give them; the hard, close-textured peat that has had *Heather* growing on it is wholly unsuitable for *Ixoras*. In this kind of soil I never saw them make half the growth that they should. Rather than use peat of this description I would pot them in good turfy loam with plenty of vegetable fibre in it, shaking out half the earthy matter before using it. Few plants are so persistent in pushing their roots down to the bottoms of the pots amongst the drainage, and in removing this more than ordinary care should be used so as not to injure them. With care in this respect there need be no hesitation in potting such as want it, even if there is a crop of flowers on them nearly ready to open, as if the roots are not disturbed more than is necessary it will have no perceptible effect on the bloom. Pot moderately firm, give a little shade when the sun is powerful, and keep the atmosphere close and fairly moist afterwards.

CALLICARPA PURPUREA.—Though this plant is seldom met with, it is one of the most effective of all the berry-bearing kinds. Its flexible shoots, when laden with their highly coloured fruit, are very effective when used in a cut state with Ferns or other green foliage, and the plant is equally attractive during the lengthened period that the berries remain fresh on it. Cuttings that were struck some time ago and have since been put into little pots should, as these become moderately filled with roots, be moved into others from 8 inches to 9 inches in diameter. The plant will grow in either peat or loam, with a little sand and some manure added. Stop the shoots so far as seems necessary to ensure a sufficiently close condition of growth; it is not desirable to have the plants too dwarfed, as they look better when allowed to grow to about 2 feet or 2½ feet in height. Ordinary stove temperature, with a moderately humid atmosphere and air in like quantity as given to other occupants of the stove, will answer for them. Use the syringe freely every day, and stand the plants well up to the glass. Old specimens cut back freely after the berries are faded should, when they have broken into growth, have the balls so far reduced as to get all the soil away that can be removed without unduly interfering with their roots. A little more room may be given, but it is not desirable to have plants of this character in pots that are too large, as the effect produced by the presence of several medium-sized examples is better than a few large ones. Where there is any deficiency of stock, cuttings may now be put in. Young, soft shoots, when a few inches long, will strike treated in the usual way.

GREENHOUSE.—TUBEROUS BEGONIAS.—Like most other things that become popular and that are easily raised from seed, the number of named varieties of these plants is now so numerous that a selection of the best becomes perplexing, especially as individual tastes differ in the matter of shades and colours. The aim of most of the best growers who raise new sorts in quantity appears to have been directed to the production of varieties—double as well as single—that bear enormous flowers; but, taking all properties into account, varieties that bear medium-sized flowers are the best. A stout, robust habit of growth that will enable the plants to hold their shoots erect with little support is essential, and a disposition to push up several growths from the bottom is equally important, as where the plants run up with a single shoot they get more or less into a straggling condition before the end of the blooming season. Large old tubers that were started some time ago will now have made considerable progress. If the pots in which they

were started do not seem large enough to keep the plants growing to the end of the summer, others a size larger should at once be given. Yet it is not well to overdo them in this direction, as this section of *Begonias* will do with somewhat less root room than some things, especially if manure water is given after they have got well established. From the time the tops begin to move, the plants should be kept where they receive plenty of light; without this it is useless to look for the best results in the shape of close compact growth and an abundant head of flowers. Young plants raised from seed sown in heat early must be well attended to, being careful not to let them stop too long in little pots; 5-inch or 6-inch pots, according to the size and strength which the plants have now attained, will be large enough for them this season. A good strain of seed such as now obtainable may generally be relied on to produce varieties that will bear well-formed flowers. The young stock ought to be grown in such a way that the plants will be in a condition to admit of a correct estimate of their habit and the character of their flowers being formed. With this object they must have plenty of room, and to prevent the growth getting drawn they should be stood close up to the glass until they come into flower.

T. B.

FERNS.

W. H. GOWER.

GLEICHENIAS.

THE whole of the plants included in this genus of Ferns are very beautiful and thoroughly distinct in their general appearance. They are widely distributed throughout the tropical world, and have been divided into two groups, viz., true *Gleichenia* and *Mertensia*. The plants in the former group to which we confine these remarks are characterised by a wiry creeping rhizome, rigid opaque fronds, which are more or less dichotomously divided, the pinnules being linear, pinnatifid, and the ultimate divisions or pinnae small, orbicular, and for the most part revolute at the margins. The members of the true *Gleichenia* group are all natives of the Australian continent, New Zealand, New Caledonia, and a few other neighbouring islands. Their general appearance is admirably represented by the accompanying illustration. Under cultivation these plants have in some instances attained dimensions of 5 feet and 6 feet in diameter; their fronds are indefinite in length; naturally they scramble amongst low shrubs and bushes, oftentimes forming dense, almost impenetrable masses.

On account of the long, wiry rhizomes these plants throw out, and from which the young fronds rise, it is at once evident that surface space is of more importance than depth, and as the plants increase in size, boxes will be found more adequate to their requirements than ordinary pots. Drainage is of the greatest importance to the well-being of *Gleichenias*, for the moment this becomes choked, the fronds assume a rusty hue, and the plants are permanently disfigured. These plants, like all Ferns, enjoy a copious supply of water to their roots, but they are not improved by overhead sprinklings, and although they are usually designated greenhouse Ferns, it will be found most conducive to their health at this time of the year and until their growth is mature to give them the temperature of a warm greenhouse or intermediate house, and during the winter months also slight warmth is essential to their well-being. During the time they are growing the plants should be kept near the glass, exposed to sun and light, but as the sun increases in power they should be well shaded from its scorching rays.

In some instances *Gleichenias* are grown in soil principally composed of fibrous peat, and this, we believe, is congenial to some of the tropical kinds belonging to the *Mertensia* group; but for the true *Gleichenia* section the soil should consist of good turfy loam, leaf-mould, and a good portion of sharp sand. *Gleichenias* do not readily reproduce themselves from spores under cultivation, although some few Fern growers have been tolerably successful in this way; but the most frequent method of increase is by division. This is effected by cutting the rhizomes through with a sharp knife and allowing them to remain until each portion becomes well rooted. The best time to divide them is early in spring, just before the young fronds

slightly downy, but the fronds are smooth; the segments or pinnae are small, bright green on the upper side, paler below. It comes from Tasmania, and thrives in a lower temperature than most of the other kinds.

G. DICARPA LONGIPINNATA, which we here illustrate, was introduced by Mr. B. S. Williams, of Upper Holloway, and in whose nursery this and many other kinds are just now in admirable condition, treated to the warmth of an intermediate house. It is distinguished from the previous kind by the great length of the pinnules, by its fronds having a metallic tint of blue over the bright green of the upper surface, whilst beneath they are glaucous; moreover, it is said to be much freer in its habit of growth. It comes from Australia, but the particular district is not stated.

somewhat high temperature during its season of growth.

G. SEMIVESTITA is found in New Caledonia and Malacca, and enjoys the warmth of an intermediate-house all the year round. In habit it somewhat resembles *G. microphylla*, from which, however, it is easily distinguished in a growing state by the dense rusty red branches when in a young state, being somewhat more lax in its growth, and by the pinnules being longer.

G. HECISTOPHYLLA.—This is a New Zealand plant with much-branched fronds and long pinnules.

G. SPELUNCÆ is a distinct, somewhat lax-growing plant. It does not appear to grow so freely as any of the other kinds. It comes from New South

Gleichenia dicarpa longipinnata.

begin to rise. There is a considerable similarity in this section of plants, and hence those who study them in the herbarium only in a dried state are apt to be misled by not being able to distinguish differences which are easily defined when living plants are examined, and although these differences may not be of sufficient importance to constitute specific rank, a distinguishing name is requisite for garden purposes. It must be confessed that *Gleichenias* are about the most difficult plants in the whole Order to grow into good healthy specimens, but this fact should never induce a lover of plants to discard them, more especially as they present such a unique and charming appearance when success is achieved. The following kinds are all deserving the careful attention of Fern growers:—

G. CIRCINATA, perhaps better known by the name of *microphylla*, is found in New South Wales and Tasmania. The stems and branches are sparingly furnished with short rusty hairs.

G. CIRCINATA GLAUCA, also known in gardens as *G. Mendeli*, differs from the preceding in its more robust habit of growth, in the thick coriaceous texture of its fronds, and by the beautiful whiteness of the under side of the segments, which, combined with the deep green of the upper side, renders it one of the most beautiful, while at the same time it is one of the rarest. It is said to come from New Zealand.

G. RUPESTRIS is a native of New South Wales, and by general consent is considered the handsomest of the true *Gleichenias*. It is a bold-growing plant, the stems reddish purple; fronds much ramified and dense. This kind appears to enjoy a

Wales and Tasmania, and varies considerably from different localities.

A natural picture.—At the close of last week, when the strong west wind was carrying over huge masses of rain-laden clouds, I saw towards evening one of the most beautiful of natural and all too fugitive pictures upon which the eye could rest. Away to the east hung a grand background of intensely blue-black cloud, colours such as an artist could hardly portray without charge of exaggeration. Suddenly the sun burst through the clouds in the western sky, and there sprang out from the bank of cloud a magnificent bow glowing in hues of luxuriant radiance, whilst above it was seen its reflection hardly less brilliant than the bow itself. In the background beneath rose up tall Chestnuts, Elms, and other trees, now rich in their green shades of leafage; beneath these

were scores of Apple trees in glorious bloom; still beneath these in the foreground, the rich denser green of the Currant and Gooseberry bushes, and in the immediate foreground flowers of many hues and forms. Through one part above the bushes might be seen the diverse green tint of a field of young wheat. The picture was all too fleeting, but endured for a few minutes, the sun lighting up each leaf and flower with a wondrous glow of colour enhanced by the humidity of the atmosphere. We hear or read of the wondrous beauty of scenery found in other countries. I doubt whether within the moderate radius over which this picture extended any other view could excel it for variety and beauty. So much of colour and beauty enclosed in a double framework of rainbow is rare, and merits description.—A. D.

KITCHEN GARDEN.

W. WILDSMITH.

POTATOES.

THE long-continued cold weather is most harmful to the Potato crop, and is seriously discounting its prospects. Generally, the plant growth is three weeks later than in average seasons, and a check through coldness of soil and general lowness of temperature is very harmful to the tubers and their growth. Over large areas of ground, from tubers planted some seven or eight weeks, growth is not yet visible, or but just pushing through, and the cold nights with fierce winds and rains are not helping development. There is, of course, ample time for development, and when warm weather eventually comes that growth may be rapid, but all experience shows that slow growth at first, checked by cold, is rarely productive of abundant crops. The early kinds will be perhaps most seriously affected, because these are always the most tender, and being checked are no longer early; hence we shall probably see the second early or mid-season sorts turning in so close upon the heels of the first earlies that the chances of these latter being rendered profitable are doubtful. We have before us in this matter plain evidence of the effect of climatic forces upon our gardening labours. It makes no difference if we plant at the usual time, and go on in our usual routine just as if the weather would be favourable at our bidding. We have had little seriously discouraging weather this spring, for frost has spared the abundant bloom on the trees, but still there has been such a continuation of low temperature that growth is wonderfully slow, and the summer, such as it will be, must inevitably be a short one. Experience serves to show yearly how dependent our garden and field crops are upon sunshine, and failing warmth there exists no power or policy the which can adequately make amends for the loss lack of warmth entails. But the efforts of the Potato grower must of course be bent upon rendering to his checked crops what help he can, and in no way can that assistance be better rendered than in stirring the soil freely between the rows of plants, admitting sun-heat, and by pulverising the surface enable the roots to run freely and form tubers readily. Free motion of the surface soil is wonderfully helpful, but except where there is ample space between the rows it must not be too deep. Potato plants root much nearer the surface than is usually supposed to be the case, and large growers who send their horse hoes deeply set through their Potato fields whilst moving the soil literally show little regard for the stolons of the roots. Ordinarily, in fields rows are too close together, probably from 24 inches to 27 inches. In such case not more than 6 inches width of the intervening soil may be moved to a depth of 1 inch, whilst the surface nearer the plants should not be worked deeper than 2 inches. Where a space of from 30 inches to 36 inches between the rows is given—none too much in good soil for strong-growing kinds—much greater liberty may be taken, and in gardens, stirring the intervening soil with a fork to a liberal depth may be safely indulged in with good results.

One common fault in Potato cultivation is in too liberally heaping up soil about the stems early, and

often burying or injuring the foliage. We are pretty well agreed as to the value of earthing up the plants. By its practice we give the stems support in rough weather. We keep the tubers under the surface, and thus prevent them from greening and being by exposure rendered unfit for food. We protect them also appreciably from the ill effects of heavy rains when the disease spore is prevalent, as it is well known now that these minute bodies are washed into contact with the newly forming tubers and penetrate the tender skins direct as readily as they do the leafage; thus moderate and careful moulding affords some appreciable protection from that evil. Then in large broadths very often it is not possible to get up the crop until long after the plant growth has decayed. Earthing up assists to find the rows; indeed, very markedly designates them, and is most serviceable even in that way. Altogether, experience has shown that earthing or moulding has many valuable features, and it seems probable that we shall not forsake the plan at present. Those gardeners who are blessed with warm sheltered borders and soil that is deep and rich find the production of early Potatoes less difficult, because they can provide artificial aids. Still, even these cannot compensate for lack of sun warmth. They, too, are ever in search of first early kinds, if any such can be found, which will give good crops with quick returns. Still there seems to be a limit to the earliness of the Potato plant, as the old Ashleaf remains one of our very earliest, though by no means one of our most productive kinds. For garden work or where the soil is light and warm Mid-summer Kidney has been found very early, large-tubed, and productive, and the more it is grown the better it is liked. In fields, however, the American Beauty of Hebron is the most favoured because it is fairly hardy, and if not of first-class quality at least is early and productive. On dry soil its quality is far better than on wet ones. Its white-skinned sport, White Beauty, or Duke of Albany, is also becoming highly favoured. There is still a useful field open to raisers for the production of really first early Potatoes. A. D.

Late spring Broccoli.—This useful vegetable has this season been unusually late, for even in this southern part of the kingdom capital close heads of Champion and Eclipse, and other late types of Broccoli are still plentiful. The heads now being cut are from seed sown in May last year, and put out after Potatoes came off, without any digging or manuring of the ground. They were dwarf and small-looking when winter came on, but if the stems are stout it is surprising what fine heads they will develop in spring.—J. G. *Hants.*

Ruby Rhubarb.—The description given by Mr. Lloyd to the Rhubarb he has under the above designation seems to be very applicable to that high-coloured kind, Hawkes' Champagne, or perhaps to Johnstone's St. Martin, both excellent early sorts. It may be but a local seedling so named, but then we know that Rhubarbs reproduce themselves almost so faithfully, that real deviations from established kinds are rare. Perhaps Mr. Lloyd would not mind next autumn sending a root to the Royal Horticultural Gardens, Chiswick, where it could be tried against all the best-known kinds, and if found distinct and meritorious, would certainly receive its meed of praise. Naturally, on hearing of any good thing said to be new, we wish to learn how far it may be so, and also whether really distinct from standard kinds.—A. D.

Failure of early Potatoes.—"E. C. M." has probably satisfied himself ere now that his early planted kidney Potatoes were not dead, but sleeping. Even so far south as the metropolitan area, which is usually regarded as early in the matter of Potatoes, very few of the earliest sorts planted in March before the last snowfall are through, or, in any case, coming only with exceeding irregularity. This lateness is entirely due to the coldness of the soil, which still remains cold so far that runner and dwarf Beans lie longer in the soil before germinating than I have ever before noticed, and the plants now are coming so irregularly, that large growers

are fearful of comparative failure. Then I observe that all early Peas sown before the snowfall have come very unevenly; indeed, in many cases not more than one third of the seed has germinated, whilst later sowings show a first-rate plant. Broad Beans are looking well also, but these are indifferent to cold. Generally, all vegetables, but especially those of a tender nature, are late and irregular.—A. D.

NEED PEAS BE STAKED?

GARDENERS in private places are so accustomed to regard the sticking or staking of their Peas as an indispensable part of their culture, that quite probably the above question will be a surprise to some of them. We have always staked our Peas ourselves, as much from habit, I am open to confess, as anything else, for I am not quite persuaded that sticks are necessary to ensure a good crop. I notice every year that, although we give our Pea rows the maximum amount of room—that is the height of the sticks or more, viz., 3½ feet to 6 feet or 8 feet—the Pea haulm, as a rule, overtops the sticks, the taller sorts often growing to the height of 9 feet, and hence the best bearing portion grows over to the lee side and hangs down quite off the sticks, and often gets very much broken and injured in high gales. The same thing happens elsewhere. I observe the height of the Peas varies according to soil and culture. But what I wish to point out is that the Pea haulm appears to grow taller the taller the sticks are, being drawn up, as it were, by the partly shaded position. I want to put the question therefore—Do Peas need sticks to produce a good crop? Would the plants bear well enough without them, and, if so, why stick them? I saw last year a grand crop of tall field Peas, quite as tall as some garden kinds, that bore as fine a crop as anyone could desire; and I know a raiser of garden Peas who uses few or no sticks for his crops, although he has a greater interest in getting good crops than gardeners have in private places. The rows just lie on the ground and support themselves, producing plenty of flowers and pods, and not growing very tall.

Sticking Peas is the most expensive and troublesome part of their culture. Our rows require each, at least, 400 sticks, which cost us 1s. 3d. per hundred in the wood, another 1s. 3d. to fetch home, trim, and sharpen; 1s., at least, per hundred to put to the Peas and carry off the ground again in autumn, which make 3s. 6d. per hundred, or 14s. per row, not to speak of labour caused in stirring the ground and cleaning up after sticking. One-third of our crops—say the dwarf earlies—are staked with the best of the old sticks shortened of their decayed ends and re-sharpened; but the remainder and later Peas have new sticks every season. In plenty of gardens 50 rows of Peas are nothing unusual, and the total cost of sticks and sticking cannot be much less than £30 annually. Good Pea sticks are readily saleable on most estates. We can never find sufficient for our customers, so that they must not be reckoned as of no account in the home garden. I put aside the cost of culture in other respects, and leave the gardener to find out how much he is in pocket in his Pea crop by the sticking practice. W.

Broccoli with variegated foliage.—I send you a specimen of Broccoli with variegated foliage. Two years ago a similar plant came in a row of, I think, Barr's Mayflower. I saved seed, and have now two rows of beautiful plants, about 75 per cent. being variegated, some perfectly white. You have no idea how pretty the rows look—quite equal to a row of variegated Kale. I may claim something for it, too, in the way of hardiness, for when I tell you we had sixty-three frosts in the first quarter of the year and twenty-three more in April, with the thermometer at 15°, you may judge we have not had summer weather. Of course, the severity of the winter has somewhat damaged the plants, and the heads are not so good as otherwise they would have been, for the original plant bore a very fine head. I should have sent a specimen to the Horticultural Society's meeting, but Tuesday is an awkward day for us who are so far away. We have to

run the risk of packages arriving too late for the committee. In cooking, the variegation of the foliage is of course lost, but the effect of a row in the garden is very pleasing, and as the quality is quite equal to other sorts, it is, at any rate, worth preserving. —A. RAWSON, *Windermerre*.

. A very striking variegation.—Ed.

KITCHEN GARDEN NOTES.

CAULIFLOWER AND BROCCOLI.—We have made the last planting of Early Dwarf Erfurt Cauliflower and a first one of Veitch's Autumn Giant. The latter variety, in addition to its other good qualities, will also continue for a long time in a usable condition; that is, the heads do not quickly burst open, even if left on the ground, whilst if lifted and boiled in on a north border it remains good for a very long time, thus rendering frequent successional plantings of the variety unnecessary. It also stands the heat of summer better than any other variety, but to the other extreme—frost—it soon succumbs, so that it cannot be depended on later than November, and therefore to succeed it, and which will probably be ready as soon, the first planting of autumn protecting Broccoli has been made, and other plantings of the variety will follow as soon as ground becomes vacant, and will be closely succeeded by plantings of Early Penzance and Snow's Winter White.

SAVOYS AND COLEWORTS. All our ground is so fully cropped, that we have been compelled to plant a small batch of Savoys down the centres of the rows of Potatoes; such double cropping is not to be commended, and ought not to be had recourse to except under very pressing circumstances, as, apart from the plan being somewhat of a lottery as regards the well-doing of the Savoys, the Potato haulm is likely to get trodden down, and of course the crop suffers proportionately. In the present instance the Potatoes, being our earliest open-air lot, are in such a forward state of growth, that we have no fear of such a result, but if planted amongst late kinds, great care will need to be exercised to guard against injury to the plants by the haulm overtopping them, and of injury to the plants from treading down the haulm when doing what is necessary to keep the Savoys in good growing condition. We have also made a planting of Coleworts that will come in useful at the end of summer and during early autumn when French Beans and Cauliflowers begin to get scarce, and these occupy space on an east border between rows of seedling Asparagus that are wanted for permanent planting next year. The lines of Asparagus are 30 inches apart, and a single row of Coleworts is put down the centre 9 inches from plant to plant. Early London is the variety, and they are planted in shallow drills.

CELERY.—Planted the earliest batch in double lines a foot from plant to plant. Having been pricked out on a shallow bed of soil the bulk of it leaf soil—the plants moved with good balls, and being planted carefully, there is no trace of check to growth, and therefore little danger need be feared of the plants bolting or prematurely seedling, this state in most instances, and with most vegetable crops, being the result of a check in the early stages of growth. The spaces between the rows of Celery, the soil of which will presently be needed for earthing up, are for the present cropped with Radish, Lettuce, Spinach, and Turnips, all of which crops rapidly mature, and will therefore be off the ground before the soil is needed for earthing up.

POTATOES.—Despite the cold and backward season, these have come up well, and the earliest Ashleaf, planted at the foot of a south wall, will soon be fit to dig. Two or three of the handsomer varieties, as well as some seedlings that are being grown for trial, have had the weakest portion of haulm pulled off, two and in some instances only one strong shoot being left. By this means, if we do not get numbers we get the finest tubers, and can the better form an opinion as to the merits of each variety. The present is a good time to apply artificial manures; to some on poor ground we have applied a dressing of soot, and the refuse—burnt ash—after sifting out the charcoal, we use for potting purposes. Earthing up is an unnecessary

operation, and we only practise it from necessity, that is, to protect the haulm from frost and to prevent the tubers being exposed to the light and greening, owing to shallow planting. On retentive soils the practice of earthing up is desirable, but it is the opposite on light land.

HERBS.—Planted out seedling kinds that were raised in heat, which include Knotted and Sweet Marjoram, Chervil, Basil, Thyme, and Sage; old plants of the two last have been cut back to keep the plants full of young shoots. Tarragon and Mint are constantly kept in bushy growth by the longest shoots being regularly cut for use.

GENERAL WORK includes the sowing of Veitch's Perfection and Ne Plus Ultra Peas, and of Canadian Wonder Dwarf French Beans. Thinned out those first sown to a foot apart and slightly earthed them up. Made another sowing of Paris White Cos Lettuce, and also made the principal sowing of Turnips. A piece of ground with a northern exposure is the most suitable on which to grow Turnips in the summer-time; on such an aspect they is never very troublesome. W. W.

CHRYSANTHEMUMS.

E. MOLYNEUX.

PLANTS which had received the protection suggested in my last notes will present a much better appearance than those which were standing unprotected and in the full force of the terrible hurricane experienced last week. I hear of many plants which had of necessity to stand out in the open which are now in a sorry plight, the leaves in many instances being so broken and whipped that they are now rendered useless, and in consequence the plants must receive a serious check.

Plants that have been grown from cuttings struck at the times I have advised, and have been grown by being shifted into larger pots as required, placed in cold frames, and attended to in the matters of airing and allowing sufficient room, will now be ready for their final shift into the pots in which they are to bloom. In a former number of THE GARDEN I gave the sizes of pots which I considered the best for the various styles of growth under which the plants were being grown, and for the information of new readers I will shortly repeat the sizes of the pots I gave. To have blooms of the finest quality for exhibition or home use 9-inch pots are the best for single plants, and two plants may be placed in an 11-inch pot. For large specimen-trained plants 11-inch and 12-inch pots are suitable sizes. Single varieties and Pompons may be grown in 8-inch and 10-inch pots, the last size being suitable for ordinary conservatory use. It is not possible for Chrysanthemums to produce the finest flowers upon plants which are soft and sappy in their growth. The branches as they grow should become solidified and in time partly ripened, or failure is the consequence when the blooms are required. Well-ripened wood always yields flowers of the finest order of merit, such as size, solidity, form, and colour, and power to remain in perfection the greatest length of time, and this is influenced considerably by the manner in which the plants have been cultivated. All the difference, then, is made in producing what is required and aimed at, and what is not wished for, through the perfect or the imperfect manner in which the final potting is performed. To the inexperienced growers potting these plants is of no more consequence than any ordinary soft-wooded plant. Pot them loosely, and they will grow strongly and produce large leaves and stems which will be devoid of that solidity which is essential to success; this, then, is in my opinion

one of the chief causes of failure. To have growth which will develop suitable flowers, the soil should be rammed very firmly with a blunt stick. In soil of a light character it is hardly possible to pot too firmly, but it is not so necessary with heavier soil, as the water will not percolate so freely, and should the drainage become defective, trouble may ensue through the soil becoming waterlogged. When the plants are potted firmly the growth is not so rapid early in the season, but it is rendered solid and firm as growth proceeds, and is more likely to mature its branches in a wet autumn through the growth being slower and of a harder kind during the summer months. The pots and the crocks used for drainage should be perfectly clean, and the latter should be free from any grit. Careful and free drainage is essential to success; it is common in some places to throw the crocks into the pots in a careless manner, but I find when the operation is carefully and properly performed, success is more likely to follow. For the largest pots 2 inches of drainage is not too much, allowing a little less for smaller pots. The piece placed in the bottom of the pot should be much larger than the hole and quite hollow, and smaller crocks placed over this. Over the drainage place a layer of the roughest parts of the compost to prevent the fine soil running down, and thus preventing the free egress of water. The best material for this purpose is pieces of thin newly cut turf, as this does not decay so soon and is not so liable to clog the drainage. Where the soil is of a heavy character use less turf over the crocks and add a few fresh leaves and some charcoal. On soil of a light nature sprinkle a small quantity of soot; this prevents to some extent the ingress of worms when the plants are standing out of doors, and the soot also acts as a stimulant.

The soil should be firmly rammed down with the blunt end of the stick previous to placing the plant thereon. Do not cover the top of the ball of soil attached to the plant previous to this shift too deeply; just add a little to cover any roots which may have become bare through watering, but leave a depth of about 1½ inches to allow space for water and top-dressing at a future opportunity; if the soil is moist (as it should be at potting) no water will be required for three or four days, after which time a good soaking may be given if the weather be dry, but an occasional wetting of the foliage with the syringe will be found beneficial in the afternoons of fine days. After potting is completed the plants are generally placed together in a snug corner, as it is yet too early to stand them thinly in their summer quarters, as more cold easterly winds are almost sure to take place, which do a vast amount of harm to the newly potted plants. There are many excellent varieties which cannot, owing to their delicate constitution, be dispensed with altogether, and at the same time do not succeed thoroughly under the same treatment as do the ordinary kinds; therefore any extra trouble that may be spent upon such sorts will be well repaid in the end when the blooming season comes around; these varieties I will class as weak growers, and for the information of those persons who do not know them, I add a list of them, selecting only those which are meritorious. One reason of their weakness is, that they do not, of course, make roots in the same proportion as the stronger growing sorts, and therefore pots a size smaller should be provided for them; neither will they require nearly so much water at the roots at all stages of their growth as those of stronger growth. The soil should also be of a lighter character than for the ordinary hardier and more robust kinds. To render the compost suitable,

add to that previously recommended more leaves, charcoal, wood ashes, and sand, taking care that no loam only that which is fibry shall be used; removing the fine by sifting carefully; do not pot quite so firmly, and add a little more drainage. It is a good plan to place such plants as require special treatment as that named by themselves, as they are more likely to have better attention, as regards watering, than when placed along with the bulk of the plants; stimulants can be more easily applied to the plants in proper quantities. Such delicate kinds do not make so many roots, and, therefore, cannot assimilate strong stimulants in the same proportion as can the stronger growing sorts.

The next important matter to consider is the selection of a suitable site for the summer season where the plants can have the full benefit of the sun all day, and still be protected from east and south-westerly winds. These latter often play sad havoc amongst the plants during the month of September, just at a time when the buds generally are swelling, and when the points of the shoots are soft and easily snap off by the force of the wind, thus causing much disappointment. Of course, those plants which must from necessity be tall to produce the finest blooms suffer the most, but all kinds do the same more or less. Select a position away from the immediate shade of overhanging trees, which tends to render the plants weakly and prevents to a large extent the wood becoming sufficiently ripe. For those plants intended to produce large flowers, and which naturally grow tall, no better position can be found than by placing a single row of plants on the side of a path running east and west in the kitchen garden; or one row on each side of a broad path running north and south answers admirably, as, where such positions can be afforded, the plants can be easily attended to in watering and regulating their growth during the summer; but where this is not convenient and the plants have to stand together, select the most favourable site, placing the rows running east and west and at such a distance apart that the shade caused by one row of plants does not fall upon the row behind. To effect this, a distance of 5 feet between the rows should be allowed. If the space at command is of such a size, that several rows may run parallel to each other, the tallest growing plants must be arranged at the back with the dwarfer in front. This should be attended to both for appearance sake and the welfare of all the plants. Means must be taken to secure the plants firmly in position when they assume natural heights. There are several ways of effecting this, which I will describe in another issue. The foundation on which the plants rest should be well drained, that no superfluous water lies about; a thick layer of ashes answers this purpose, and also retains a cool, moist bottom, which is beneficial to the plants during the summer months.

LIST OF WEAK GROWING VARIETIES.

	<i>Anemone.</i>
	Fleur de Marie
	Mlle. Cabrol
	Madame Cloz
	Sœur Dorothee Souille
	Princesse of Anemones

Plants grown in the "bush" form or as trained specimens should be secured from the winds, as a disfiguration of the foliage in these cases means almost ruination to their appearance. Where the space is of sufficient size they may be arranged together in one block, allowing sufficient space between each plant for attending to their requirements of watering and regulating the growths. A layer of ashes also should be provided whereon the pots may stand in this case also.

TREES AND SHRUBS.

W. GOLDRING.

THE SNOWDROP TREE.

(HALESIA TETRAPTERA.)

THE COMMON NAME Snowdrop tree is known to all who take an interest in trees, yet the tree itself is not at all common, and it is only in old gardens that mature specimens of it can be found. It is a very old tree in English gardens,

The Snowdrop tree (*Halesia tetraaptera*); flowering and fruiting twigs with detached flowers and fruit (natural size).

having been introduced from South Carolina as long ago as 1756. It is very pretty when in bloom where it succeeds well, but it fails to thrive in most places, it being somewhat tender and peculiar in its requirements. At the best it is but a small tree, rarely exceeding 20 feet in height, forming a wide-spreading and rather dense head. The form of its foliage, flowers, and fruit is so well shown in the accompanying engraving, that a description of the tree is unnecessary. It is an early flowering tree, being in full bloom in this country about the latter part of May. A plant of it profusely laden with bloom has an aspect different from all other hardy subjects, as each bloom is pure white, bell-shaped, or, in fact, like a miniature Snowdrop. It is decidedly partial to a moist soil and situation, and the finest tree I have seen of it was growing by the side of a lake, where no doubt the roots were perpetually moist. In dry soils it forms a mean, scrubby tree, and does not flower so profusely. It likes shelter from strong winds, but fails if the situation is shaded. It is, in short, a most desirable and interesting tree, one that I should always plant if I wished

to have trees out of the ordinary run. Good plants of it may be obtained from the best tree nurseries for 1s. 6d.; therefore there is no reason why it should be so seldom planted. There are two or three other kinds of Snowdrop tree which are perhaps only geographical forms of one species. *H. parviflora*, a native of Florida, is an old introduction, but not such a desirable tree as *H. tetraaptera*, and the same may be said of *H. diptera*, which is found in Georgia and Carolina.

Prunus Pissardi.—If "J. C. C.," in THE GARDEN (p. 474), expects this *Prunus* to bear purple-coloured flowers, he will be disappointed, for it is now generally recognised as a variety of the Myrobalan Plum, and, in common with the type, the flowers are pure white in colour. At the same time opinions differ as to the season of the year at which this *Prunus* is seen at its best, for while the writer of the article in question extols the beauty of its unfolding foliage, the dull purplish green tint is to me by no means attractive, and I think that this shrub is seen only at its best during the latter

half of the summer and early in the autumn. When the roots are in a fairly cool, moist soil, and the head of the plant fully exposed to the sun, it acquires by August a depth of colouring that renders it a formidable rival to the best forms of the purple Beech. I tried this *Prunus* for forcing earlier in the season, and though it was very pretty from the profusion of its white blossoms, the dull purplish foliage played but a small part in the embellishment of the plant. That *Prunus Pissardi* is a great acquisition to our hardy shrubs is now fully recognised, but, in my opinion, its prominent features must be sought during July, August, and a part of September rather than in the earlier months of the year.—T.

Akebia quinata.—This pretty Japanese climbing plant is bardy in some parts of England, and around London it will survive most winters if protected by a wall or other shelter, but it is as a greenhouse climber that it is seen at its best, and extremely pretty and useful it is for that purpose. The small claret-coloured flowers are borne just now in great profusion, and the divided foliage, which is of a bright green tint, is also very pleasing. It is a slender climber of rapid growth when once established, and is best when but little tied or cut in, for then, where sufficient space exists, it will form

graceful festoons, and always bears a light and elegant appearance. Perhaps at no time is it more attractive than when allowed to take possession of a neighbouring shrub, as it will quickly establish itself thereon. This Akebia certainly displays its charms to a much greater advantage when grown in this way than if secured to a wall, as cold, cutting winds late in the spring are very apt to injure the expanding foliage. It is a plant of easy propagation, for cuttings of the young shoots if selected from the small short-jointed ones, rather than those that are stout and succulent, will root without difficulty, and in addition to this suckers that may be detached with a few roots are often pushed up from the base of an established plant. In the case of these last they had better be potted and kept close and shaded for a few days till they recover from the check. The Akebia can also be propagated from root cuttings, but this method is seldom followed, as the young shoots strike so readily.—H. P.

MYRTLE-LEAVED LAURELS.

THE best thanks of the readers of THE GARDEN are due to your correspondent "W. G." for his interesting descriptions of choice trees and shrubs. Keen observers living in the neighbourhood of London or the great southern nurseries may, if they will, make themselves thoroughly acquainted with many, if not all, of these gems; but scores of young men far away in the country are less fortunate, and for this reason this part of your paper is especially valuable. Last week, at page 498, you gave an illustrated description of the Myrtle-leaved Portugal Laurel, a shrub, by the way, which hundreds of young gardeners have never seen nor noticed, and yet it is one of our most handsome and useful hardy shrubs for varied purposes. Here we have used it extensively for forming groups in lieu of Kalmias, which do not thrive on our limestone, and many clever men until close upon them have been led to believe we had a knack of growing these chaste plants to perfection. Being thoroughly hardy, compact, and dense, it is admirably adapted for screens, low shrubberies, and hedges, always provided the knife in lieu of the shears is used for pruning purposes. Having myself manufactured perfect cones 10 feet in height and 6 feet in diameter at the base, I can endorse all that has been said of it for this kind of work, also for standards. Indeed, of all the shrubs I have met with, I know of nothing to equal it—that is, as a thoroughly hardy shrub for formal purposes. Bays, as a matter of course, from a classical as well as a gardenesque point, stand very high, and figure high if we wish to buy them, but this Laurel is quite capable of taking care of itself in the most exposed places through the sharpest winters; it is most tractable, and may be grown to perfection by those who cannot winter Bays, as it does not require protection. When left alone and other shrubs are kept at a respectable distance, this Laurel assumes a half globular form, and makes a growth of about 9 inches annually, the bright purple of its young wood and its dark leaves giving it a most beautiful appearance. Pyramids and standards of course require annual pruning, not only to keep them in perfect form, but also to increase their density. The best time to do this I find is about the end of August or early in September, early or late according to the season. The buds then become prominent, but do not break until the following spring. This cold, late season with us they are just pushing. W. COLEMAN.

The Purple Barberry.—Among shrubs remarkable for the purple hue of their foliage, and that show this peculiarity in a marked manner directly the young leaves make their appearance, mention must be made of this variety of the common Barberry (*Berberis vulgaris*), for it is very attractive even in the spring, especially under such conditions as I saw it a few days ago, viz., in close proximity to a specimen of the yellow-leaved variety of *Spiraea opulifolia*, the branches of which were studded with the little golden rosettes of expanding foliage, and the peculiarity of each shrub was greatly heightened by its direct contrast with the

other. Like the typical form of the Barberry, the purple-leaved variety will grow almost anywhere, but the depth of colouring is much intensified when the plants are grown fully exposed to the sun.—T.

ORCHIDS.

W. H. GOWER.

BRASSIA ANTHEROTES.

THIS plant belongs to a section of Orchids which has been much neglected since the advent of the numerous *Odontoglossums*. There are, however, several kinds which are showy and deserve the attention of Orchid lovers, and the species here named is one of the best. *Brassias* are free-growing plants, producing somewhat flat pseudo-bulbs and persistent evergreen foliage, so that they are ornamental even when not in flower. They should be grown in an intermediate or Cattleya house. These plants should be potted or basketed in rough fibrous peat and Sphagnum Moss; they enjoy an abundant supply of water and free exposure to light during the growing season. The supply of water should be considerably reduced during winter, but care must be exercised at this time in order to prevent the plants from shrivelling, for should this occur it is very detrimental to them, sometimes ending fatally. *B. antherotes* attains a height of about 18 inches, and produces its spike of bloom from the base of the mature bulb in the month of May. The raceme is nearly a foot long, and the individual flowers large and conspicuous, the sepals and petals being lengthened into long tail-like points; these are yellow, blotched and spotted towards the base with dark purplish brown spots; lip large, caudate, clear yellow, spotted with brownish purple and bearing an orange-coloured crest.

ORCHID NOTES.

IN many collections of Orchids, *Dendrobiums* are to be found of a sickly appearance, wanting that deep green colour of the foliage that betokens constitutional vigour. I allude specially to that good old species *D. mobile*, also such handsome deciduous species as *D. Wardianum*, *D. crassinode*, *D. Bensoniae*, &c. They are mostly of easy culture if they receive the right treatment. Most of them have now passed out of bloom, and it will be observed that the young growths have made considerable progress. At a certain stage of the development of the young growths, roots are freely emitted from the base, and as soon as this takes place, or even before, the temperature of the house should be very high and moist; the plants themselves should by no means lack a plentiful supply of water at their roots. This treatment will cause a vigorous and healthy growth, which, as the season advances, must be matured by free exposure to light. I have had the plants close to the glass with the sun shining directly upon the house at four in the afternoon, the ventilators closed and the temperature 100°. We remove the plants from the Cattleya house, and place them with others requiring the same treatment. *Cattleyas*, of course, would not like it, but they also prefer a higher and rather moister atmosphere while making their growth. The weather has been very cold and still continues in that state; therefore we have not yet removed several species to the cool house that are usually placed there early in June. These are *Odontoglossums Phalenopsis* and *vexillarium* and some of the *Masdevallias*, such as *M. tovarensis* and the *Chimaraoid* section. In fact, unless a brisk fire is maintained, the temperature of the Cattleya house falls from 50° to 55° at night—a low minimum for May. We are potting various occupants of this house. If the operation is carefully performed the plants receive no check, as fresh roots are speedily formed and the new compost infuses renewed vigour into them. We repot most of the *Cattleyas* once in two years, and by that time the roots have grown so

much and cling so firmly to the inner surface of the pots, that it is necessary to break the pots to pieces in order to save the roots from injury. We now make a practice of potting most of the *Dendrobiums* at this time; it ought to be done just before the roots begin to push out from the base of the young growths. Small plants of these are potted annually, large ones once in two years, but those not potted are surface-dressed. Fumigating to destroy green fly and thrips may be practised in houses containing principally *Cattleyas*, *Laelias*, *Dendrobiums*, but *Odontoglossums* should be removed from the house. The temperature of the *Cattleya* house now should be 55° to 60° at night.

Repotting may also be continued in the warmest house. It is a good time to repot *Odontoglossum Roezli* as the plants go out of bloom. This beautiful Rose-scented species makes a mass of small fibrous roots, and speedily makes good any injury caused by transferring the plants from one pot to another; quite the largest proportion of the potting material for these should be clean Sphagnum Moss, the remainder the best fibrous peat with clean drainage and charcoal. Another of the occupants of this house, not always so well grown as it ought to be, is the beautiful *Oncidium ampliatum majus*; this species lasts so long in flower, and the colour is such a clear golden yellow, that no collection should be without a few plants of it. When in flower and for a few weeks afterwards, the plants are comparatively at rest, requiring but little water; but as soon as they start into active growth, a high stove temperature is necessary, and the plants may be placed close to the glass roof. I have felt the leaves when the house had been shut up, and the shading removed in the afternoon, and they have been quite hot. It is well adapted for pot culture, and soon grows into a handsome specimen plant. Another class of plants we are now repotting is the *Cypripedium*, such as *C. Stonci*, *C. Lowi*, &c. Those who have made up specimens from single plants in small pots, may have noticed that in two or three weeks the new roots have pushed freely, and even if they are again taken out and repotted, the plants grow on freely without any apparent injury. I remember some ten years ago visiting a large establishment where the making up of specimens for the Manchester exhibition was practised, and the gardener pointed out to me *Cypripediums*, *Masdevallias*, &c., growing with the greatest vigour. The plants had been turned out of their small pots, placed in large ones for the exhibition, and again they had been returned to the small pots. Year after year this practice was successfully carried out. I do not state this as approving of the system, but merely to show how quickly Orchids can recover from any injury to the roots at the height of the growing season. Of course, after repotting the temperature must be kept up and a corresponding moist atmosphere also. 65° to 70° at night is the lowest, rising to 85° or even to 90° in warm weather as a maximum. J. DOUGLAS.

SHORT NOTES.—ORCHIDS.

The Scorch'd Orchid (*Orchis ustulata*) has been sent to me in splendid form from the Pyrenees by Mr. Allen. It is larger and finer than any I have seen produced in this country.—A. D. WEBSTER.

Ceologyne Dayana and C. Masaegeana.—These are both in flower in Messrs. Veitch's nursery, in the King's Road; they are quite distinct from each other, and yet the pendulous spikes have a striking resemblance; in colour and form the sepals and petals of *C. Dayana* are much narrower and more weed-like. Both species should be in every good collection of Orchids, as they flower well and grow so freely.—J. D.

Orchis mascula.—From Cork we have just received a gathering of the above Orchid, which shows that the climate of the south of Ireland is well suited for the cultivation of this pretty, early-flowering kind. Some of the flower-stems were unusually strong and with fine, closely-set flowers of every shade from pale lilac to deep purple. They were kindly sent by Mr. Blair, a chemist in Cork, who seems to devote considerable attention to this pretty and interesting tribe of plants.—A. D. WEBSTER.

Destruction of crickets.—Can any of your readers inform me how to get rid of crickets? I have the charge of

greenhouses, a small range of which closest to the heating apparatus is principally used for propagating and is infested with swarms of this insect. They eat cuttings and the young leaves and shoots of a variety of plants to an extent scarcely credible. I have used Chase's paste (wafers), pans filled with oil, &c., to little or no advantage, while numbers are nightly killed in the pathways and on ledges of the brick-work, &c.—H. C.

MR. J. BRITTEN AND THE DICTIONARY OF ENGLISH NAMES OF PLANTS.

TO THE EDITOR OF THE GARDEN.

SIR,—As the compiler of this dictionary, I feel called upon to say something about a gross misstatement respecting it to which my attention has been directed in the introduction to the recently published "Dictionary of English Plant-Names" of Messrs. James Britten and Robert Holland, where, to the mention of my book in a descriptive list of works on plant-names, is appended the remark: "Most of the names are inventions; the local ones seem largely taken from parts I and 2 of the present work."

No part of this assertion is honest; the first clause of it is, in fact (I have to speak plainly), a downright and malignant falsehood. The names given in my dictionary are no inventions of mine, but are the result of many months' laborious research through the pages (as stated in my preface) of "our standard botanical works, British and colonial floras, the leading horticultural journals, and the catalogues of British, American, and Australian nurserymen"—of every publication, in short, that seemed likely to afford any help on the subject. As for the local names of British plants, which Mr. Jas. Britten now more cautiously says "*seem* largely taken from parts I and 2" of his work [he formulated this charge in more unqualified terms when he made the circumstance of my not having specially mentioned his work a pretext for attacking my book two years ago in his *Journal of Botany*], I have to say that the names of British plants form but a very small portion of the names in my book, and nearly all of them were taken by me from authorities which were quite as open to me or to anyone else as to Mr. Jas. Britten.

My book was most favourably reviewed by the Press with hardly any exception from the *Times* down, the *Gardeners' Chronicle* (no mean authority) pronouncing it "the most complete dictionary of the kind hitherto published." I believe the only unfriendly notice of it appeared in the *Journal of Botany*, edited by Mr. James Britten. I may here observe that, as Mr. Jas. Britten's dictionary contains but few plant-names except those of British plants, the obscure local appellations of which constitute its special subject and *raison d'être*, its title as "A Dictionary of English Plant-Names" is a most inappropriate and deceptive one, readily leading anyone unacquainted with the book to imagine that it deals with the full range of English plant-nomenclature, which, in its wider application to plants of all countries, my "Dictionary of English Names of Plants" attempts, however imperfectly, to embrace.

With criticism which fairly and honestly pointed out defects in my book I should be very far indeed from finding any fault. I must protest, however, against Mr. James Britten's last slanderous misrepresentation.

WILLIAM MILLER.

Rating of nurseries.—It is announced that a public meeting of nurserymen will be held at the Horticultural Club, Henrietta Street, Covent Garden, on Tuesday, June 28, to consider the excessive rating of nurseries, and to agree on a combined action in an endeavour to procure the reduction of the assessments. The chair will be taken at 4 p.m. by Mr. T. Wood Ingram, of the firm of Wood and

Ingram, Huntingdon. The meeting will be held under the auspices of the Nursery and Seed Trade Association, and the Horticultural Club have kindly lent their rooms for the occasion. The secretary is Mr. F. Goodchild, 25, Old Jewry, E.C.

SOCIETIES AND EXHIBITIONS.

MANCHESTER HORTICULTURAL.

LOVERS of the beautiful have a rich treat provided for them at Old Trafford. Several large marquees and a huge glass and wood structure are filled with plants and flowers of great beauty. All the leading local cultivators and many of the principal nurserymen in the country have sent some of their best specimens, and the show, as a whole, can only be characterised as beautiful in the extreme. No money prizes were awarded, only jubilee medals of gold and silver. A marvellous display has been made, and in all departments of the show, with perhaps the exception of stove and greenhouse plants, the exhibition was a fine one.

As there was no schedule, and consequently no grouping together of rows of plants of the same kinds, there was more scope for artistic arrangement. The formality of an ordinary exhibition was avoided, and a series of beautiful pictures was presented to the view. Orchids and herbaceous plants were most abundantly illustrated. Messrs. James Dickson and Son, of Chester, occupied a space of 300 square feet with herbaceous and alpine plants.

A beautiful and interesting group of Orchids was contributed by Messrs. F. Sander and Co., of St. Albans. Amongst these was a plant of *Maxillaria Sanderiana*, grand forms of *Lælia purpurata* and *Cattleya Mossiae*, *Oncidium hastatum* Roezli, *O. Schillerianum*, *Odontoglossum Pescatorei*, the ever welcome *Odontoglossum Alexandrae*, *Cypripediums*, *Dendrobium thyrsoiflorum*, &c. These were arranged with exquisite taste, while overhead were suspended baskets of *Odontoglossum citrosum*, &c. A very fine group of *Masdevallias* from the gardens of the Duke of Sutherland, Trentham, was staged by Mr. Blair. Opposite to it was a fine collection of *Begonias* from Messrs. J. Laing and Son, which were alike remarkable for size, brilliancy of colour, and variety.

An enormous collection of 300 plants of *Cattleya Mossiae* belonging to Mr. Wrigley, of Bury, contained many fine varieties. Messrs. Cutbush and Sons, of Highgate, also contributed a nice collection. These consisted of *Azaleas*, *Ericas*, *Aphelexis*, *Tetrathecas*, *Azalea mollis*, *Ferns*, *Oranges*, and the handsome, but much neglected *Leschenaultia biloba* major. The Liverpool Horticultural Company exhibited some fine Orchids, such as *Dendrobium nobile*, *Cattleya Mossiae*, *Lælia purpurata*, *Odontoglossum Alexandrae*, &c. The principal feature of the group from Messrs. R. Ker and Sons, of Liverpool, was the handsome, well-bloomed plants of *Azaleas*. A collection of *Pitcher* plants from Mr. Joseph Broome comprised *Nepenthes Mastersi*, *N. robusta*, *N. Dominiana*, *Sarracenia Fielderi*, *S. Flambeau*, *Swani*, *Maddisoni*, *Sesteriana*, and others. A miscellaneous collection exhibited by Mr. B. S. Williams, Holloway, consisted of Orchids and other stove and greenhouse plants, amongst which were fine plants of *Dendrobium nobile*, *Dendrobium thyrsoiflorum*, *Odontoglossum vexillarium*, *Masdevallia Veitchii*, *Amaryllis Empress of India*, a grand variety; *Anthurium Scherzerianum*, *Boronia elatior*, and other fine plants. A fine group of British and exotic hardy Ferns was exhibited by Messrs. Birkenhead, of Sale, and a grand collection of plants from the gardens of Mr. Joseph Broome, consisting of Orchids and other plants, conspicuous amongst which is a fine plant of *Vanda teres*, bearing upwards of 100 blooms, *Azaleas*, *Lælias*, &c.

Messrs. James Dickson and Son, of Chester, exhibited a fine collection of herbaceous plants; amongst them were *Lilium Harrisii*, *Doronicum plantagineum excelsum*, *Daffodil Sir Watkin*, *Anthurium Liliastrum*, *Tulipa cornuta*, *T. retroflexa*, *Thalictrum anemonoides*, *Primula obconica*, *Paeonia tenuifolia flore-pleno*, *Androsace sarmentosa*, *Cum-*

panula Warneri, *Phlox Nelsoni*, *P. stellaria*, *Gentiana verna*, *Anubria violacea*, *Sempervivum spinulosum*, *Omphalodes Luciliae*, *Ranunculus alpinus*, *Cistus florentinus*, *Cypripedium Calceolus*, *C. spectabile*, *C. pubescens*, *Phlox canadensis*, *Lychnis Lagascae*, *Celsia Arcturus*, *Sempervivum triste*, *Gladiolus Rosy Gem*, &c.

A group of *Pelargoniums*, show, fancy, and zonal, came from Messrs. Hylance and Son, which grouped together produced a nice effect. Mr. S. Schloss, of Bowdon, sent a collection of stove and greenhouse plants, amongst them being grand specimens of *Bougainvillea glabra*, *Anthurium Scherzerianum*, *A. crystallinum*, *Azalea Criterion*, *Latania borbonica*, *Alsophila capensis*, *Rhododendron Sesterianum*, *Clerodendron Balfourii*, *Enchisar grandiflora*, &c. The centre of the tent was devoted to circular groups of plants, amongst which the *Roses* of Messrs. Paul and Son were conspicuous. These consisted of standards, half standards, and dwarfs; the most notable were fine plants of *Sunset*, *Junno*, *Etoile de Lyon*, *Her Majesty*, *Grandeur of Cheshunt*, *Madame Clemence Joigneaux*, *Jean Ducher*, *Souvenir d'un Ami*, *Niphetos*, *Dr. Andry*, &c. Messrs. Francis and Arthur Dickson and Sons, of Chester, sent a group, the chief features of which were *Rhododendrons* and herbaceous plants; whilst the best group of *Rose* plants ever exhibited by an amateur in Manchester came from Mr. J. Brown, of Heaton Mersey. It was a Jubilee collection of fifty plants, the most notable being *Perle des Jardins*, *La France*, *Madame Gabriel Luizet*, *Madame Clemence Joigneaux*, *Madame Lambert*, *Merveille de Lyon*, *Beauty of Waltham*, *Marie Van Houtte*, *Sunset*, *Comtesse de Sereyue*, *Ulrich Brunner*, *General Jacqueminot*.

A very nice collection of herbaceous plants was contributed by an amateur, Mr. Mellor. Amongst these were fine plants of *Sempervivum Lageri*, *Saxifraga peltata*, *Primula Munroi*, *Lychnis alpina*, *Armeria lauscheriana*, &c. There were also good collections of show and fancy Pansies. There was a very beautiful collection of cut flowers, bouquets, wreaths, &c., from Mr. Mason, of Sale, and Messrs. Perkins, of Coventry. The former contained some very novel combinations. Conspicuous was a basket of *Maréchal Niel Rose* with *Lilacs*; in another the same *Rose* and white *Lilac*; a basket with *Lily of the Valley* at the back and dark *Roses* in front; also a basket with white *Lilacs* and dark *Roses*, all of which were lovely combinations. Messrs. Perkins had a magnificent wreath of white flowers, comprising *Richardia*, *Stephanotis*, the *Vale Lily*, *Lilium longiflorum*, and *Eucharis*, relieved with *Maiden-hair Fern* (*Adiantum cuneatum*). Bouquets were both numerous and beautiful, the introduction of a few blooms of *Masdevallia* amongst light flowers producing a very happy effect. Boxes of cut blooms of *Pelargoniums* were contributed by Messrs. Pearson and Son, of Chilwell. There was also in this tent a fine exhibit of hybrid *Aquilegias*, or *Columbines*.

Death of Mr. George Jackman.—We regret to announce the death, at the Woking Nurseries on the 29th ult., of Mr. George Jackman, at the age of fifty. He attended the last show of the Royal Botanic Society, where he caught a cold, which turned to inflammation of the lungs. Mr. Jackman succeeded some years ago to the business carried on by his father at Woking. His name is well known in connection with the *Clematis* raised by his father, and perpetuated in the variety known as *C. Jackmanni*. Mr. Jackman, along with the late Mr. Thomas Moore, was author of a work on the "*Clematis* as a Garden Flower" a very good book.

WOODS & FORESTS.

"YORKSHIREMAN."

RIVEN J. SAWN OAK STAKES.

It is not generally known that riven stakes are stronger or tougher than sawn ones, although sawn stakes are cheaper, because they can be cut out for about half the cost of riving. Riven stakes always run with the grain. If the tree be naturally bent, so also will the stakes be. The saw, on the other hand, cuts straight through the bends and does not go with the grain in any case, unless the timber is perfectly straight, and when such stakes come to be driven into the ground they break off at these points. Those who have fences of this kind should remember this. Riven stakes, in my opinion, look just as well as sawn ones, or better when regularly set up and lashed together with small wire rope twisted between the stakes. Three-inch by 2-inch riven Oak stakes lashed together in this manner make a strong, enduring fence without any stays, except one at each end or at intervals. There are between 500 and 600 yards in 1 cwt. of galvanised iron rope, No. 6 and 7 gauge, and such rope is very cheap—cheaper than any other kind of top rail or bindings. There is an art in putting it on. The stakes are first driven into the ground as evenly as possible; then starting with two strands of rope at one end where it is securely attached, the man gives it several plaits between every two stakes, bringing one strand round one side of the stake and the other strand round the other side; then plaiting as many plaits again the reverse way, and so on. By this device, bringing each strand hand over hand for its whole length, a thing almost impracticable, is avoided, as the twist is done and undone between every three stakes. A man and boy can make and put up a great extent of such fencing, making the stakes and all, and as only unsaleable Oak is used for the purpose, a cheaper and better fence could not easily be contrived for all ordinary situations, such as in fields and round woods. Hereabouts the farmers capped the stakes with sawn Larch or Spruce rails, which soon rot and give way, but one or two examples of the wire-rope-stayed fence seems likely to lead to the abandonment of the old plan. Galvanised staples are used with the wire here and there.

FORESTRY NOTES.

NATURAL GAME COVERT.—This is, by most sportsmen, considered superior to that formed artificially, but as the woods in which it will become anything like serviceable must be well thinned out, more so, indeed, than is necessary for cultivated underwood, it is, perhaps, less seldom seen in a truly efficient state. Light and air are the great essentials to underwood generally, but that of spontaneous growth in particular, so that to have really first-class game preserves the plantations must be kept well thinned out, far thinner in most instances than is really necessary for the profitable cultivation of timber. Brambles and Bracken are about two of our best natural woodland plants for forming game coverts, they soon becoming, under favourable circumstances, dense, warm retreats for either the pheasant or the hare. Where the former is not so plentiful as is desired it may be readily enough increased either by seed-sowing or planting out two-year-old seedling plants, either of these methods being found well suited for the plant in question. Old plants may likewise be used, but the per-centage of deaths is usually great, even where a more than ordinary amount of care has been expended on lifting and planting. Bracken may be readily enough established in any open woodland by transferring squares of soil with the

roots therein to the places intended to form clumps, but a much better, cheaper, and far surer method is to raise seedlings, and when two years old to plant them out with the sods of earth intact. The Blackthorn is likewise well adapted for covert, and succeeds well in good light loam and an open situation; Gorse also does well in similar places, but all the better where rough stones are freely commingled amongst the ordinary soil. In dampish, peaty woods, Heather is a valuable covert plant, as is also the Bilberry and Crowberry. Rough Grasses, too, are not to be despised, more especially where other stronger growing plants, such as the Brier and Thorn, help to support these, and prevent their rotting by coming in contact with the ground. Grass in a withered state is a favourite resort of game generally.

FILLING UP HOLES IN TREE STEMS.—Far too frequently it happens that in old specimen hardwood trees the trunks are rendered unsightly by holes caused either by natural decay of the wood or an accident, and when such trees are growing in conspicuous positions and the wounds near the ground level, they become most unsightly, and steps should at once be taken to set matters right, whether by removing the trees or filling up such holes in the stems. Apart altogether from being unsightly, such holes exercise a powerful influence in causing rottenness throughout the whole stem in which they occur by forming as it were inlets for water. To fill up such holes is easy enough, and after repeated experiments we find the following method of doing so to answer better than any other previously tried. Scrape out and remove every particle of damp decaying matter from the hole, fill it with dry, broken brick-bats, cement the surface evenly over with the bark, and paint it as nearly the colour of the bark as possible. Several diseased holes so treated on old Oak trees in the park here could now hardly be noticed, and I have every reason to believe that from the number of years since the experiment was tried and the present healthy appearance of the trees, that the filling up of such holes has had a wonderful effect in staying and arresting disease and rot. The experiment is both cheap and simple, so let everyone who has an eyesore of an Oak with a holed stem set about filling these up at once with old brickbats and cementing the surface with concrete. Nailing a piece of zinc over the hole has been tried, but however carefully this may be done, dampness is sure to set in and ruin the stem. Clefts between upright-growing branches, that are but harbours for rain water, may be treated similar to the Oaks above described, and the surface of the concrete tarred over, this latter having likewise a wonderful effect in keeping out damp and preserving amputated limbs and smaller branches from contracting rot.

CULTIVATION OF THE MISTLETOE.—When we consider the amount of money spent annually in importing Mistletoe from the Continent, one is naturally led to ask the reasonable question, Why not cultivate it ourselves and be independent of foreign supplies? That this could, to a great extent, be done is no doubt true, for it is well known to everyone who has thought of the subject that the Mistletoe thrives luxuriantly in many parts of England. It is, moreover, readily enough cultivated by simply rubbing the glutinous berries on the smooth—not rough, as is usually recommended—surface of the bark of many trees, but particularly the Apple, and protecting these from birds until the plants get well established. I have never noticed any ill effects caused by the Mistletoe to the Apple trees on which it is grown, and on applying for information on this head to a friend who cultivates it lovingly and largely, he tells me that he has not noticed any either, although some of his finest trees have had several large plants growing on them at the same time. If this be true in all cases, then the suggestion for the extended culture of the plant in suitable districts is worthy of consideration. It is generally believed that the Mistletoe is not found either in Scotland or Ireland, but such is a mistake, for I have frequently seen it in the latter country growing on old Apple trees; while several stations in Scotland might be named for it. From a record I have

kept for several years, I learn that the Mistletoe is by no means confined to the Apple, nor Oak either, for my list, with stations, reveals the fact that this parasite has been found growing on many other trees.

THE EVERGREEN LABURNUM (*Piptanthus nepalensis*) is a fairly good shrub for planting in the open, but when used beneath the shade of large trees its appearance is anything but desirable. Having an overstock of this plant in our home nursery, we transplanted a number of strong, healthy, 5-feet high specimens to thin and open, though partially shady woods, but the results are not up to expectations; indeed, I am fully convinced that the common Scotch Laburnum is a superior plant for this purpose to the *Piptanthus*. Let no one, however, undervalue this shrub for planting in open, sheltered situations contiguous to drives and walks, and where its abundance of conspicuous yellow flowers that last so long through the summer months is always welcome, for in such situations it is certainly a pretty and desirable plant. Seeds are usually produced abundantly, and as these germinate very freely and grow away rapidly into large plants, a good stock wherewith to experiment upon as to the suitability of the plant for various parts of the country is thus speedily got up. It is too tender for many situations, but along the sea-coast and in warm inland places it does well, and here I cannot remember a single plant being killed or even cut back by the frost.

FAGOT-MAKING. This is a simple and profitable way of utilising waste forest produce, particularly the smaller branches, that cannot well be converted into or sold as firewood. Instead of burning up all prunings, therefore, it may be wise policy on the forester's part to first of all find out if a market for disposing of such when made into fagots for oven-heating and fire-lighting is not to be had. Here, where for home consumption the number of fagots used annually is very large, we keep a man constantly employed at the work, and find it to be a more profitable way of disposing of branches and small firewood than burning. Small fagots of about 7 inches in diameter and a foot long, and usually made of Larch branches, sell at 8s. per hundred, while those for oven-heating, and which are made of larger branches than the latter, and also of larger proportions, being about 18 inches long by 10 inches broad, sell at 10s. per hundred. Larch branches are found to be preferable to most others for making small fagots, as when dry they burn quickly and do not emit sparks, at least to any great extent. They should be carted home as made in the woods, stacked for a few weeks, and finally housed until wanted for use.

A. D. WEBSTER.

Transplanting in winter.—Although, as a rule, I am not in favour of transplanting Evergreens during the winter months, still, if the weather continues mild, Aucubas, Rhododendrons, Box, and plants of this kind that always lift with good balls of earth, may be moved with comparative safety; and there may be special reasons why such work should be done. When such is the case, those trees that have been so frequently removed as to have induced plenty of fibre may be operated upon with every prospect of success, provided the weather does not turn out too cold and cutting. April is of all others the safe month for transplanting Evergreens, and any choice specimens should be left till that time. Of all Evergreens, Rhododendrons are perhaps the most beautiful; but as it is generally supposed they will not succeed in any other than peat soil, many are deterred from attempting to grow them. The want of peat need be no obstacle to their cultivation, as they will grow in any sharp clean soil that has not been much under cultivation. The best, perhaps, for this purpose are the trimmings of banks and turf from the sides of roads and paths, which contain plenty of sharp grit. The trimmings from the roadside, or any soil that may be used, must not contain chalk, or it will be fatal to success. If choice plants are planted, and peat can be obtained at a moderate cost, it is worth while to give them a start in this material. To do this, a hole should be dug large

enough to hold a bushel or so, in which the plant will get a good hold, and be independent of the surrounding soil for a year or two. Failing this, leaf-soil about half decomposed may be used in the same way. In planting, make choice of moderately moist and partially shaded situations, as Rhododendrons will not bear excessive drought, and succeed best if not exposed to the full glare of the sun.—J. G.

THE BEECH.

(FAGUS SYLVATICA.)

THIS tree is justly admired for its stately crown and beautiful green foliage, which renders it a desirable ornament in parks and large pleasure grounds. It is found in most parts of Europe, and is one of the handsomest and most valuable of our forest trees. Its trunk is erect and massive, and its height is usually from 100 feet to 130 feet. The roots spread for 10 feet or 12 feet round the tree, but none of them go deeply under the surface, except the tap-root, which penetrates perpendicularly into the earth for 3 feet or 4 feet. The branches have a more or less upward tendency, and form a symmetrical and majestic crown.

Upon young trees the bark is of a greenish grey hue, but as the tree matures it assumes an Ash-grey colour. Both leaf and blossom buds are long, cone-shaped, sharp-pointed, and consist of eighteen or twenty brown, slightly fringed scales. The leaves, when young, are soft and delicate, and of a beautiful yellowish green colour, but as the season advances they become deep green.

In October they become yellow and dry, shrivel up, and fall to the ground. Upon young trees, however, the withered leaves often remain until they are forced off by the swelling of the fresh buds in spring. The male catkins, which are in general four to a bud, have long drooping peduncles, and consist of about twenty greenish yellow florets. The female blossoms, which appear in pairs upon the young shoots, consist of sharp-pointed catkins. The fruit, which is ripe in October, consists of rough spiny capsules, each of which contains two or three smooth triangular brown nuts.

The highest elevation at which it is found is 5000 feet above the level of the sea, but it does not seem to thrive well at a greater altitude than 2000 feet. In Thuringia and among the Harz Mountains noble Beeches, 100 feet in height, are found at an elevation of 1800 feet. The finest Beech forests in the world are situate in the island of Rügen, on the dunes of Denmark and Mecklenburg, and on the plains and low hills of Germany. It is in these regions, where Beech forests cover many thousand acres, that the tallest living Beeches are to be found. In the last century, Beeches 174 feet in height were cut down in North Germany, and at present many single trees exist there which are 135 feet high and 11 feet in circumference. Beeches thrive best in a surface-soil of poor, dry, sandy loam, with a subsoil of chalk mingled with gravel, sand, and small stones. Those trees which grow upon mountain slopes, or on low humus-covered hills, with a northern or eastern exposure, yield the best timber.

Beeches are generally propagated by means of seed, and the young trees suffer much from frosts and drought, and in damp marshy situations. Mice and mole-crickets are also very destructive to the roots of young trees.

The Beech attains its full height when about one hundred years old, and then lives in perfect vigour and health for two hundred or three hundred years. Trees of this age are generally from 10 feet to 15 feet in circumference, and contain from 10 to 12 cords of timber. A cubic foot of fresh-cut wood weighs 65 lb.; but this, by thorough seasoning, is reduced to 41 lb. or 39 lb. In damp poor soils, Beech trees frequently perish from internal rot between their seventieth and ninetieth years.

Of the common Beech some very ornamental varieties may be met with in cultivation—as, for example, different kinds of Weeping Beech, also the purple and copper-leaved varieties, and the Fern-leaved Beech, the leaves of which are cut into

narrow segments, resembling the fronds of a Fern. These are almost wholly used for purposes of ornament, for which the common Beech itself is well adapted. The products of the Beech are numerous and valuable.

The timber, which is heavy, hard, firm, and durable, is extensively employed in the manufacture of numerous implements, tools, and articles of furniture. On account of its brittleness and liability to the ravages of insects, it is seldom employed for building purposes.

Beech timber is especially adapted for sub-aqueous structures, or for positions in which it is not exposed to the action of the atmosphere. As fuel, the Beech is very valuable, and is surpassed in heat-giving qualities only by the Hornbeam and Maple. The charcoal of the Beech is highly esteemed on account of the equable heat which it emits. The bark is useful to tanners, and from the ashes of the wood excellent potash is obtained.

In Denmark, Sweden, and some parts of America the leaves of the Beech are carefully picked, dried, and used to stuff bed-ticks and pillows. The leaves and ashes form an excellent manure for Grass and Clover lands. The husks and nut-skins contain a very poisonous material known as fagin. The nuts themselves form a favourite food of some birds and quadrupeds, red deer being especially fond of them, and they are also, in some countries, boiled, dried in the open air, parched by artificial heat, and ground into meal, from which bread and soups are prepared. The nuts have a pleasant sweetish flavour, and are very oleaginous. Considerable quantities of oil, resembling Almond oil, are obtained from them by pressing. From 100 lb. of nuts 12 lb. of pure oil and 4 lb. of coarser oil are obtained. The former is of as good quality as the best Olive oil, and the latter makes a useful lamp oil. The refuse furnishes a good food for pigs. The best season for felling Beeches is the month of December. J. H. M.

GROUPING CONIFEROUS TREES FOR PROTECTION.

THE dotting style of planting is cold, as well as meagre; nevertheless it has its uses; it shows what individual plants can become under difficulties. It also brings individual specimens and species into the sharpest contrast, and thus exhibits their special characteristics in intensified and, one might almost add, exaggerated lights. It has also enabled cultivators to grow the largest number of species and varieties within a given area. Useful as a school in which something may be learned about trees, it is worse than useless as a means of improving landscape effects; nay, more, the dotting plan mars every landscape on which it is practised. What play of light, or shadow, or repose could be obtained by a series of dots, even though they consisted of trees faultless in form and symmetry? Trees so disposed might be enjoyed as specimens, but a pleasing landscape, consisting of solitary trees, is plainly an impossibility. Not only, however, is the dotting style inimical to landscape beauty, but it is also opposed to cultural perfection.

Trees and shrubs are gregarious by nature, and if we compel them to grow in solitary isolation, we must take the consequences; and we do so in the form of slow and stunted growth in summer, or of ruthless destruction by cold in winter. It is not good for trees to grow alone. Each wind that blows beats against them with full force; the sun and dry air drain each leaf and bough of its rich juices, and, worse than all, the extremes of heat and cold do their worst as regards the exposed roots. This exposure of the roots to direct solar and atmospheric influence is altogether unnatural, and consequently injurious. But there is no need to rest the case on such general statements. It is only necessary to trace the palpable effects of the frost throughout our pleasure grounds, after an exceptionally hard winter, to discover that the single trees are often cut down, while groups of the self-same sorts escape unhurt. The seeming exceptions but confirm the rule.

These exceptional groups killed or injured will

be found in a lower situation or a moister locality. In the former the air is colder, as cold air will shoot down valleys into plains with as much certainty as a stone will roll down hill; in the latter the plants are also more tender. Excessive moisture may help growth, but it hinders maturity, and it is maturity that enables plants to withstand cold. Hence it follows that groups may in such exceptional localities be cut down, while single trees at a higher level, if more thoroughly matured, may escape. But let the threefold conditions of soil, site, and maturity be alike, and the results will be wholly in favour of the groups. It is necessary, however, to bear in mind that there are "groups and groups." It is not only possible, but easy to render groups tender by overcrowding or over-feeding and when such is the case, groups may be swept away by a frost that will hardly brown the leaves of a solitary tree. It may be well to add that excessive stimulation, from whatever cause, results in weakness, that leaves the plants more liable to injury from cold than more hardy treatment.

My object, however, is to show that the conditions of growth being the same, Conifers planted in groups endure winters better than those dotted about singly. There is more than one reason for this; the tops are warmer and so are the roots. Planters can scarcely realise the amount of shelter that plants afford each other when planted in groups. I know that in a series of experiments made in Scotland, the absolute difference of temperature between the inside or outside of a wood was much less than might have been supposed. But the difference is one of air in motion or at rest, rather than of absolute superiority or inferiority of temperature. The air around and in a group is, as it were, at rest, compared with that against a single tree. Now air at rest is one of the best known non-conductors of heat; but air in motion steals it from every living or dead substance that it touches with avidity. No doubt this mere motion thwarts, to some extent, the loss of heat by radiation. But, possibly, there is sufficient gentle movement in the air of groups of trees to effect this purpose; while of the warmth and shelter the trees afford each other there can be no doubt whatever.

From many years' observation of the destructive effects of cold, I have arrived at the conclusion that most plants are crippled or killed from the roots upwards, and not from the tops downwards. This is what kills isolated trees. The best roots are often considerably beyond range of the tops. Of course, the feeding roots sweep out, and are, in ever-widening areas, in search of new and better food. Just then the frost comes down upon them with full power, and either paralyses or kills them. Old roots might be frost-proof, but young ones are not. The former deprived of the latter are as useless as detached gas or water pipes cut off from the mains. The collecting roots being crippled or killed, the main ones become useless, and the tree begins to languish and die. There is another powerful inducement to planting in groups.

The dead leaves may be left to protect the roots along with the overshadowing tops. The former, in many cases, would afford the better protection. It is astonishing how many leaves fall off Coniferae just before winter; whole barrowloads of withered leaves lie under large trees of *Pinus excelsa*, *P. Sabiniana*, *P. macrocarpa*, and others. Under single trees these are, in most cases, carefully swept or raked up, as so much unsightly litter, or are blown away by the wind. This is simply to lay the most sensitive part of the tree open to the cold. In a state of Nature these dead leaves accumulate to such an extent as to cover the ground under the trees ankle deep. They decompose very slowly, and their texture, form, and non-conducting powers are such that a very thin layer of them forms a frost-proof barrier. I have proved this, and no one who has not noted the power of the tops above and leaves below to resist cold could form a proper estimate of their potency. In group-planting there is no temptation to remove the dead leaves, and the wind is powerless to drive them out. Hence trees in groups cannot suffer at the roots, and, as a rule, they winter safely. F.

"This is an Art
Which does mend Nature: change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

GALANTHUS ELWESI AND ENGLISH NAMES.

IN reply to Mr. Wilks' and the editor's comments on my letter about the form of this species, named by them *G. globosus*, I have to say that I should not have questioned the propriety of naming it for horticultural purposes if I had been able to recognise in the figure or description any characters by which it could be certainly defined; but I do question the propriety of publishing a figure with a scientific name, which would lead anyone who did not know the species thoroughly to suppose it was a distinct new Snowdrop; when the distinctions are not capable of being figured or described, so that the plant can be recognised with certainty. As a two-flowered variety of *G. Elwesi*, with flowers more globose than the average, but not more globose than many plants of *Elwesi* in my garden, I can and do recognise it, and therefore I submit with all deference to the editor that the name I suggested, viz. *G. Elwesi* var. *biflora* hort., though it may be dog Latin, and mouthed by a narrow pedant, is, both from a scientific and from a popular point of view, a more accurate, more descriptive, and more concise name than any English one that can be devised. Snowdrops not being florists' flowers, I should not for a moment suggest that a florists' flower's name, as supposed by Mr. Wilks, would be a fitting one, such names being used only for purely horticultural varieties of popular florists' flowers, produced by florists, and not by Nature. The editor does not clearly see why I have raised the question. My reason is this: he maintains that this Snowdrop, like other garden flowers, must have an English name, though he has figured and described it with a Latin one only. I maintain that in practice he cannot carry out this theory, and that many people quite ignorant of Latin and almost without education do contrive to learn and habitually use, as most convenient, Latin names for all plants which are not florists' flowers or commonly known by English names; and I think the pages of THE GARDEN will prove that, notwithstanding the very numerous English names which he has tried to introduce, a large majority of his correspondents and the whole of the horticultural trade agree with me in this matter.

The reason why is obvious, that few of them look upon a name as anything more than a means of expressing oneself so as to be understood, and there is no way of doing this so exactly, so shortly, or so easily as by using Latin names.

You cannot get over the difficulty, except by confining yourself to talking about plants which have *bona fide* English names that everyone uses, just as I do myself, or by using an English name which is not generally known, and then explaining what plant you are talking about. And I notice that the correspondents of THE GARDEN newspaper almost invariably use either the Latin name in addition to an English one, or the Latin one alone, in just the same cases as I do.

Let us look at THE GARDEN of May 14 (p. 431) to see. I find "Plants on the Editor's Table" as follows:—

- "Wood Forget-me-not." An English plant with an English name; very good.
- "Wood Tulip (*T. sylvestris*)." Another English plant. Why a Latin name added?
- "Horsfield's Narcissus." A Latin name Anglicised. Is it any easier in this form?
- "Snake's-head." A very good name for an English flower.
- "Spring Star Flower (*Triteleia*)" I use one word instead of four.
- "Cowlips." By all means; everyone uses the name.
- "The white creeping Forget-me-not (*Omphalodes verna alba*)." Here nine words are used, and inaccuracy involved, to say what I should say, by using the Latin name alone.
- "*Primula obconica*." No English name coined as yet; very good.

"The wild Pansy (*Viola lutea*)." Surely it was not necessary to add the Latin name for this well-known plant.

"The Orange Diplacus (*D. glutinosus*)." A half-and-half name.

"*Salvia violacea*." Very good; but when the correspondent speaks of the Apple-scented *Salvia*, I do not know what he is talking about. Will he explain?

"American Cowlips." I presume some species of *Dodecatheon* is meant; but which? None of mine are out yet. Kindly give name, as I should like to have an earlier variety.

"Double scarlet Crown Anemone, crimson velvety double Primroses." Neither of these are particularly short, easy, or exact names, and I am not quite sure what I should get if I ordered by those names at a nursery.

"Yellow Banksian Rose." A name I should use myself, but not so accurate as the Latin one, which shows that the flower was named after a lady.

"Siebold's Primrose." Why better than *Primula Sieboldi*?

"*Leucium trichophyllum* or *Acis trichophyllus*." Herbert named it *Acis trichophylla*. Why use the older generic name as well, and why not add the English name, Narrow-leaved Spring Snowflake? It is descriptive, correct, and not so long as many English names, which are neither one nor the other.

"White Wood Hyacinth." Messrs. Vetch call it *spicata*. Is it distinct or not? Is it the English or the Spanish form?

"The Hoop-petticoat Narcissus." Which of them? I grow five or six fairly distinct varieties.

"Hose-in-hose and Jack-in-the-Green Polyanthus." Even the florists in dealing with such monsters as these have not quite freed themselves from the jargon of pedants.

Now, I think the editor will admit how hard it is to carry out his plan; but on going through the remainder of the paper I find the following facts:—
